

HYDROGEOLOGY OF THE
MIDDLE SIGATOKA VALLEY
SOUTHWEST VITI LEVU, FIJI

A thesis submitted in partial fulfilment of the requirements of the

Degree of

Master of Science in Engineering Geology

at the

University of Canterbury

By

Ratu Aminisitai Loco

2011

Abstract

Bedrock geology of the middle Sigatoka valley, located ~ 20 km inland of the township of Sigatoka, southwest of Viti Levu, Fiji, includes the steeply inclined Tari Formation and uplifted Qalimare Limestone of the Wainimala Group of Oligocene to Middle Miocene age. These units are juxtaposed against the steeply inclined and moderately-highly fractured Cici Sandstone and Takaro Conglomerate/Rudite of the Tuva Sedimentary Group of Late Miocene age, northwest of the study area. Surface geology is largely expressed by the sinistral Nasovatava Fault, and its associated faults splays, and unconsolidated Quaternary to Recent Alluvium that fills the incised valley. The valley includes a ~40 km² rural area, from Bilalevu to Dubalevu, characterized by semi-commercial agricultural land-use practices. This area is subject to high water resource demand and utilisation, particularly from groundwater sources. Geophysical surveys, through electromagnetic and electrical resistivity methods, at Dubalevu, Tubakeli and Bila Rd, permitted the estimation of depth to bedrock, thickness and extent of alluvial materials and the presence of fractured systems within the mapped units. Groundwater drilling, through mud-rotary circulation, permitted the characterization of the major hydrogeological units, namely surficial confining unit, alluvial aquifer system, and intermediate confining unit and fractured aquifer systems. The hydrogeological framework is capped by low permeability surficial confining unit comprising sandy silt and silty loam with 7.8×10^{-8} m/s at Dubalevu, 2.2×10^{-7} m/s at Tubakeli and 4.3×10^{-8} m/s at Bila Rd. The alluvial aquifer system, comprising unconsolidated coarse-medium gravels with some fine-medium sand in Dubalevu and Bilalevu have an estimated transmissivity and conductivity of 600 m²/d⁻¹ and 30 m/d⁻¹ and 1644 m²/d⁻¹ and 274.8 m/d⁻¹, respectively. The intermediate confining unit is composed of the fresh and unweathered sedimentary rock mass. Groundwater bore pump tests showed the fractured sedimentary system has an average transmissivity, storativity and conductivity of 10.9 m²/d⁻¹, 3.7×10^{-4} , 1.16 m/d⁻¹ for the fractured Cici Sandstone at Dubalevu, 26.2 m²/d⁻¹, 6.1×10^{-4} , 6.1 m/d⁻¹ for the fractured Takaro Conglomerate/Rudite at Tubakeli and 48.7 m²/d⁻¹, 1.7×10^{-3} , 9.1 m/d⁻¹ for the fractured Tari Formation at Bila Rd. Hydrogeochemical classification of groundwaters, springs and surface sources, showed the dominance of Ca(HCO₃)₂ type water suggesting the dissolution of calcite in the sedimentary units with variable sources of Na⁺ and Mg²⁺. Stable hydrogen and oxygen isotope analyses of groundwater, surface water and precipitation show a local meteoric water line

slope of 4.3, suggesting that water resources in the middle Sigatoka Valley are meteoric in origin with variable modifications via evaporation and mixing with older residual evaporated and connate groundwater. Chloride concentrations confirm the dominance of meteoric recharge-induced dilution. Groundwater recharge estimation, through physical and chemical mass balance models, yielded different results of 0.08 m/month (physical) and 0.2-0.6 m/month (chemical) in the wet season and -0.01 m/month (physical) and 0.1-0.2 m/month (chemical) during the dry season. Groundwater recharge mechanisms in the Sigatoka Valley, include moderate-rapidly dispersing meteoric-derived waters along fractured flow paths and seasonally variable leakage, from surface sources, dispersing along alluvial macro-pores. Groundwater protection and sustainable management in the study area is likely to be threatened by unregulated groundwater drilling, excess groundwater abstraction, absence of groundwater legislation and growing concerns of climatic variability. This thesis concludes by presenting several recommendations for groundwater protection and sustainable management, including sound groundwater exploration and evaluation of geological units, establishing an effective and sustainable legal frameworks, and increasing awareness of inherent groundwater issues such as climatic seasonality, climate change, vulnerability to contamination and unsustainable abstraction.

ACRONYMS

AAS – Alluvial Aquifer System

ADB – Asian Development Bank

API – aerial photo interpretation

CS – Cici Sandstone

Cl⁻ - chloride (mg/L)

CMB – Chloride mass balance

e - electron

EC – electrical conductivity (mS/m for EM survey and $\mu\text{S}/\text{cm}$ for chemical concentration)

EM – Electromagnetic (geophysical method)

ER – Electrical resistivity (geophysical method)

FBS – Fractured Basement System

FG – Fiji Government

FP – Fiji Platform

FMS – Fiji Meteorological Services

HD – Horizontal dipole or vertical coplanar coil orientation

ICS – Intermediate Confining System

K – coefficient of permeability or hydraulic conductivity (m/d^{-1})

LWRM – Land and Water Resources Management

MMEA – Ministry of Multi-Ethnic Affairs

MRD – Mineral Resources Department

n – neutron

NF – Nasovatava Fault (ENE-WSW trending and sinistral displacement)

NFB – North Fiji Basin

p – proton

PDW – privately drilled wells

PDC – private drilling companies

PfWG – Programme for Water Governance

PWD – Public Works Department

PWB – Physical water balance

QRA – Quaternary-Recent Alluvium

SCS – Surficial Confining System

SVRDP – Sigatoka Valley Rural Development Project

SV – Sigatoka Valley

SR – Sigatoka Rivers

S – storativity (dimensionless)

T – transmissivity (m^2/d^{-1})

TDS – total dissolved solutes

TCM – tropical cyclone Mick

TCR – Takaro Conglomerate/Rudite unit

TSG – Tuva Sedimentary Group (Middle Miocene-early Late Miocene)

VD – vertical dipole or horizontal coplanar coil orientation

WG – Wainimala Group (Late Oligocene-Middle Miocene)

YG – Yavuna Group (Late Eocene-Early Oligocene)

Acknowledgements

I am indebted to many people and parties for their overwhelming support during this research project. I would like to thank:

- (1) The Fiji Government, through the Ministry of the I-Taukei Affairs, for the opportunity granted to undertake this post-graduate program in this renown institution.
- (2) The Mineral Resources Department, particularly the (then) Director (Mr Ian Fong) and Manager Geological Services (Mr Malakai Finau), for financing this project.
- (3) My supervisors, Mr. David Bell for the advice and support throughout the research period and Dr. Travis Horton, for always having an open door to help with insights and advice on hydrochemistry, for analyzing my isotope samples and for editing this thesis. Also, thanks to Associate Professor Dr. David Nobes for his advice in the interpretation of geophysical data and for editing the geophysics component of this research.
- (4) The HYCOS program of the South Pacific GeoScience Commission (SOPAC), particularly Mr Peter Sinclair (Hydrogeologist), for permitting the use of SOPAC's geophysical equipment and for guidance on geophysical and hydrogeological investigations.
- (5) Members of the Dubalevu, Tubakeli and Bila Rd settlements for their hospitality.
- (6) The Hydrogeology staff of the Mineral Resources Department for their tireless assistance throughout the data acquisition stages
- (7) The drill crewmen who were involved during the drilling and pump test stages.
- (8) Staffs of the MRD's Geochemical Laboratory for the analysis of chemical samples.

- (9) Mr Joshua Blackstock for his assistance, particularly in the interpretation of hydrochemistry.
- (10) Mr Peter Rodda (Geologist) for confirmation of several geological questions.
- (11) Mr Jeremaia Taganesia and his family for their friendship, assistances and support during the past two years..VINAKA SIR!!!
- (12) My parents (“RATU & NAU”), brothers and sister, for all your prayers and the words of encouragement.
- (13) Mr and Mrs Sulio Vuniamatana for providing accommodation, scrumptious meals and transport for last six (6) months.
- (14) All my friends and families in Christchurch, Fiji and overseas for the encouragements.
- (15) Last but not least, my wife, Mrs Salome Loco, for her continual support in the last three years.

“VINAKA VAKALEVU”

Chapter 1: Introduction

1.1 Project background

The nation of Fiji (Figure 1.1) is comprised of more than 300 islands in the southwest Pacific (176-182°E and 16-20°S), 109 of which are permanently populated (Gale & Booth, 1993). Rapid population growth and economic development in major urban centres has increased demand, usage and exploitation of natural resources, including surface and groundwater systems.

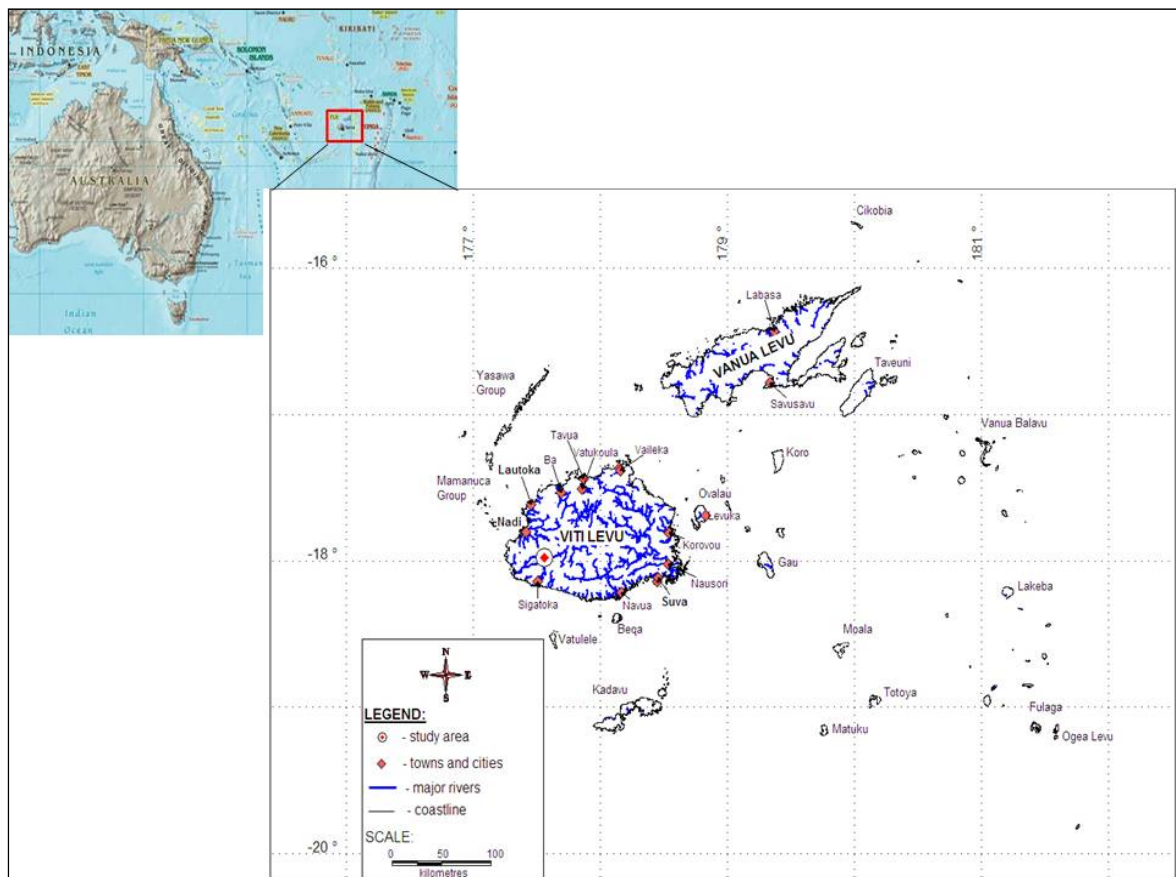

Figure 1.1: location of Fiji Islands (marked by red square) in relation to other countries in the Pacific (Henessey and iventure, 2003) and an inset of the Fiji Islands group with the study area on southwest Viti Levu in relation to the towns and cities (MapInfo Professional 10.0).

Economic activities in Fiji, primarily driven by increases in namely sugar cane farming, infrastructural development, agriculture (e.g. forestry and fishery sectors), as well as the mineral sector, has led to the expansion of urban areas, including Suva, Lautoka and Nadi (Figure 1.1). As a flow-on effect, semi-urban centres, including Ba, Tavua, and rural farming settlements in the Sigatoka Valley (SV), recorded rapid landuse changes, from traditional

subsistence farming to semi-commercial agricultural activities (e.g. root crop, vegetable, sugar cane farming). Increases in tourism had further fueled the changes, increasing stress on natural resources. If not properly monitored and managed, these changes may lead to numerous adverse environmental impacts, such as land degradation through accelerated erosion, contamination of waterways, excess demand and improper use of surface water, excess groundwater abstraction and groundwater quality deterioration via aquifer contamination.

This research was centred on two semi-commercial farming communities in the southwest Viti Levu (southern of the two largest islands in Fiji (Figure 1.1)). The farming areas, namely Dubalevu and Bilalevu, are located in the middle Sigatoka Valley. The valley, known as “Fiji’s salad bowl” due to its historical and current agricultural productivity, includes numerous aggradation landforms, namely alluvial fans, terraces and extensive flats in the central Sigatoka River (SR) valley (Figure 1.2). In an attempt to enhance the growth and supply of high-quality fruits and vegetables, throughout the year (Gale and Booth, 1993), the Fiji Government (FG) and Asian Development Bank (ADB) established of the Sigatoka Valley Rural Development Project (SVRDP) in 1986. The SVRDP intends to provide reliable and sustainable irrigation water sources to farmers in the area. In response to SVRDP, the Mineral Resources Department (MRD) conducted an investigation of hydrogeological potential of alluvial materials deposited along the meandering river during which around 21 groundwater wells were drilled across the valley (results of SVRDP will be presented and summarized in the next chapter). This thesis, however, reports on the current hydrogeological conditions present in the middle Sigatoka catchment and investigates potential deeper water-bearing units, namely fracture sedimentary basements, relative to the previously investigated alluvium deposits as per SVRDP that may provide usable groundwater quality and quantity. For ease of referencing, the middle Sigatoka valley (MSV), including the Dubalevu and Bilalevu will, hereafter, be collectively referred to as the “study area”.

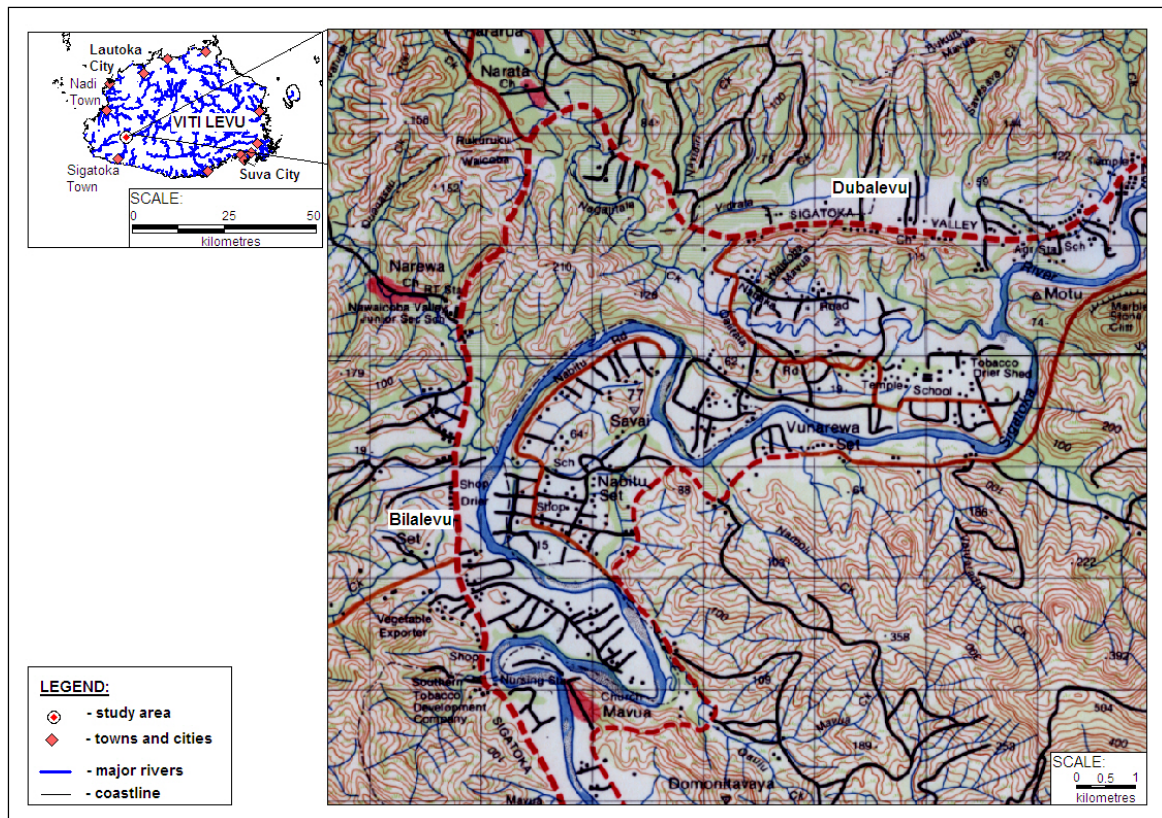

Figure 1.2: location of study area Viti Levu and an inset of the topographical map of the study area, Bilalevu and Dubalevu, with surrounding settlements and villages which were also investigated during this research through groundwater chemical and isotope sampling.

1.2 Thesis Objectives

Several key questions formed my thesis research:

- What is the general geological, geomorphic and tectonic history of the area?
- What are the relationship between this geological history and the hydrogeological conditions present in the study area?
- What are the primary recharge mechanism(s) in the study area?
- What does the aqueous geochemistry indicate about groundwater flow and local hydrological conditions?
- What are the impacts of increase human development and landuse intensification on groundwater resource quantity and quality?

In view of the preceding questions, this thesis is designed to address the following objectives:

- to classify all underlying geological materials relative to groundwater flow and storage potential;
- to examine the influences (if any) of structural controls, namely fault-induced fractures and/or shear zones in controlling groundwater occurrence;
- to determine the dimensions (extent, depth and thickness) of the underlying alluvial aquifer(s) and to locate deeper and fractured water-bearing units when present;
- to identify the major hydrochemical facies of local groundwaters;
- to determine groundwater recharge and flow regime;
- to determine the stable isotopic composition of surface water, groundwater, and rainfall relevant to local hydrological cycling; and
- to determine the sustainability of current groundwater resources utilization practices and recommend mechanisms to equitably allocate groundwater and surface water resources, particularly during the dry season

1.3 Study Area

1.3.1 Location and selection

The 40 km² study area is located ~ 15-22 km NNE and inland of Sigatoka Town (Figure 1.2). The study area had been subject to landuse intensification via rural and semi-commercial farming in the past three decades and has since, recorded an escalating demand and use water resources, particularly groundwater, for human security and safety, as well as to optimize plant growth. The selection of study areas has been made due to:

- the presence of geomorphic, geological and structural features, such as the abandoned Qalitala meander valley at Dubalevu, two abandoned (oxbow) lakes at Nabaka and Bilalevu, terraced alluvial deposits at Bilalevu, and the ENE-WSE trending sinistral Nasovatava Fault with its associated splays, suggest areas of potential groundwater storage and flow through possible buried river channels and fractured or sheared sedimentary units;

- the availability of baseline data from the SVRDP at the Mineral Resources Department (MRD) that provides essential hydrogeological constraints upon which this research can be expanded;
- continuous landuse intensification for semi-commercial and commercial agriculture purposes, which could escalate groundwater demand and use for drinking and irrigation, and potentially creates adverse impacts on groundwater resource quality and quantity;
- its close proximity to rainfall stations at Mavua and Nacocolevu, warranting a reliable long-term rainfall data necessary for physical water balance model for groundwater recharge estimation

1.3.2 Geology

The study area is underlain by Tari Formation and Qalimare Limestone of the Wainimala Group (dated Oligocene to Middle Miocene in age) and juxtaposed against the Cici Sandstone and Takaro Conglomerate/Rudite of the Tuva Sedimentary Group of Middle to Late Miocene in age (Hathway, 1989). These sedimentary units are deformed, and displaced in areas, relative to the rupture of the sinistral Nasovatava Fault (Figure 1.3.). Eustatic fluctuation in the Quaternary to Recent period caused episodic incision of these sedimentary basement upon which Alluvium materials were deposited (Davies, 1992). History and detailed classification of these geological units in relation to their groundwater potential will be examined in the proceeding chapters.

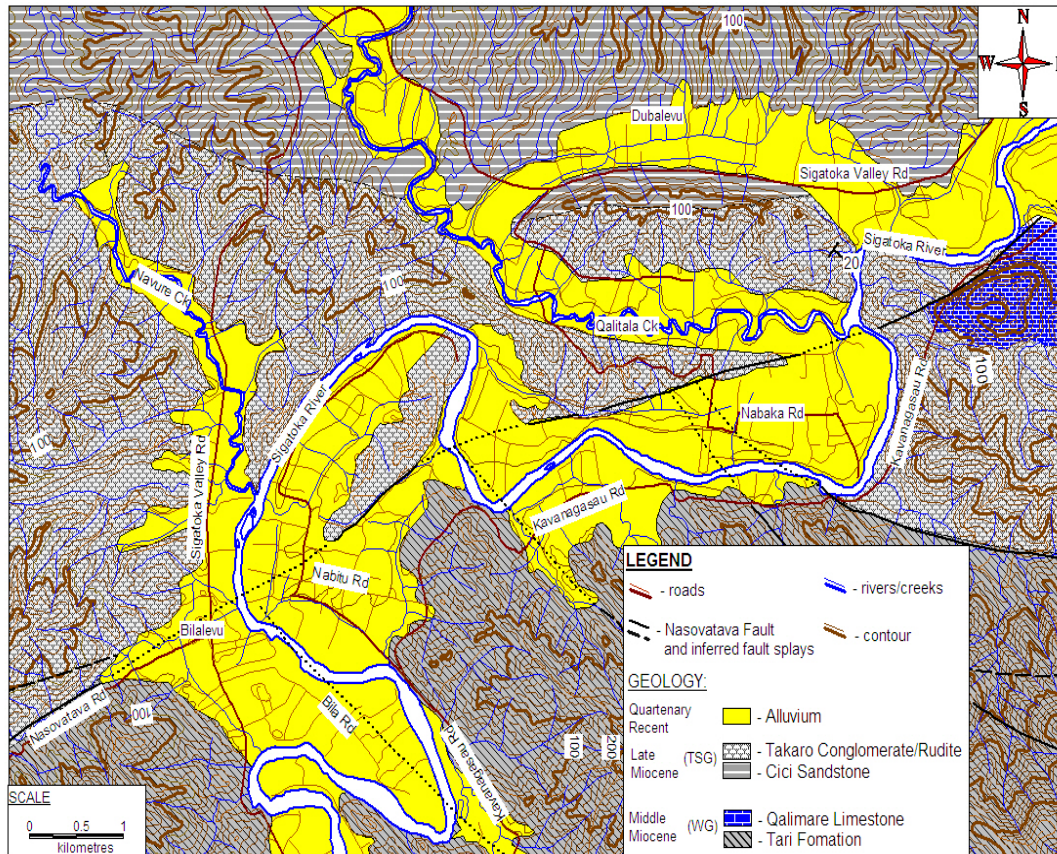

Figure 1.3: Geology of the study area comprising the Tari Formation, Qalimare Limestone of the Wainimala Group, Cici Sandstone and Takaro Conglomerate/Rudite of the Tuva Group and Alluvium materials occupying the reaches of the Sigatoka River (Hathway, 1989). Summary of the geological history and detailed classification of these geological units will be covered in later chapters. Refer to Figure 3.13 for the enlarged version.

1.3.3 Physiography

The physical landscape is characterized by steeply and highly dissected, as well as rolling, submountainous tracts (Figures 1.4 – 1.5), bounded by low-lying alluvial plains that occupy meandering reaches of the SR (Davies, 1992). The topographic high, are mantled by the uplifted and deformed Wainimala and Tuva geological groups, whilst incised valley in the study area is filled with Alluvial materials, comprising unconsolidated gravels, sands and silt.

Figure 1.4: Low resolution 1994 aerial photo showing highly dissected hills occupying the topographical highs whilst the contiguous alluvial flats, harnessed for human occupation and commercial agricultural practices, occupy the reaches of the Sigatoka River.

Figure 1.5: 1:10,000 IKONOS satellite image captured in 2005 showing highly dissected landscape with confined alluvial flats occupying the reaches of the Sigatoka River.

Overall, fluvial surface processes are the primary control on the shape of the Middle Sigatoka Valley. These processes, according to Selby (1985), include:

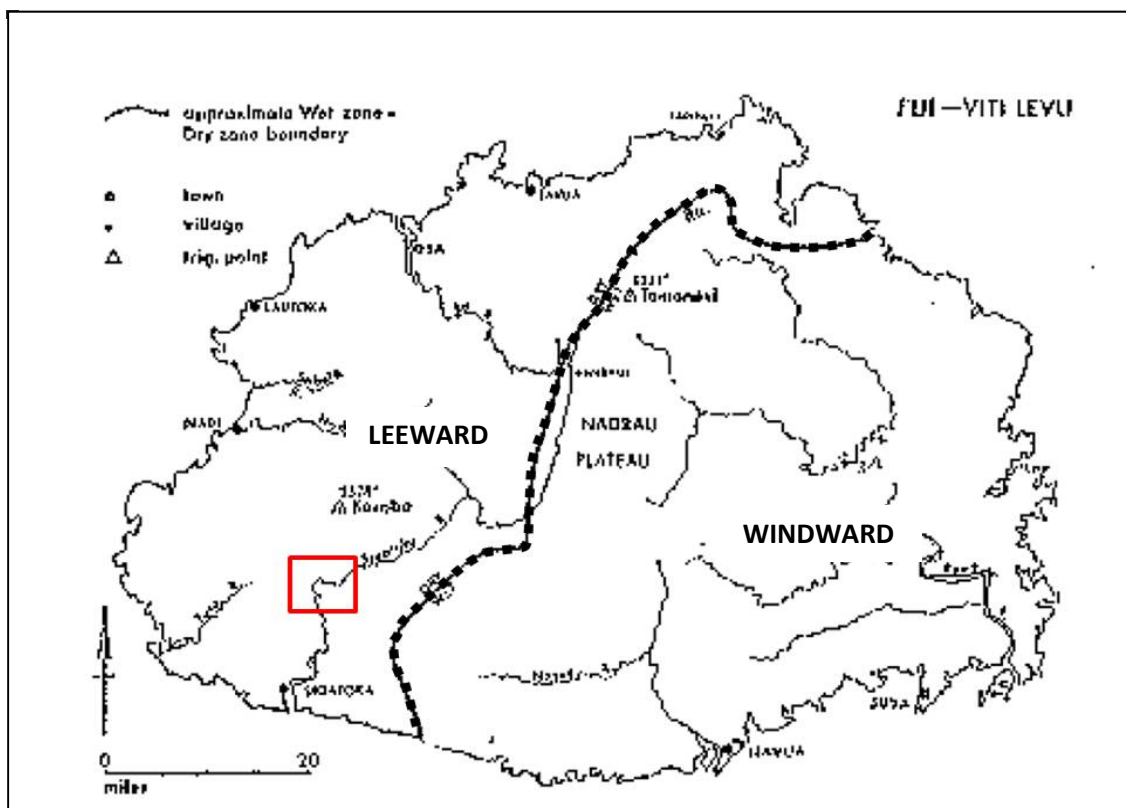

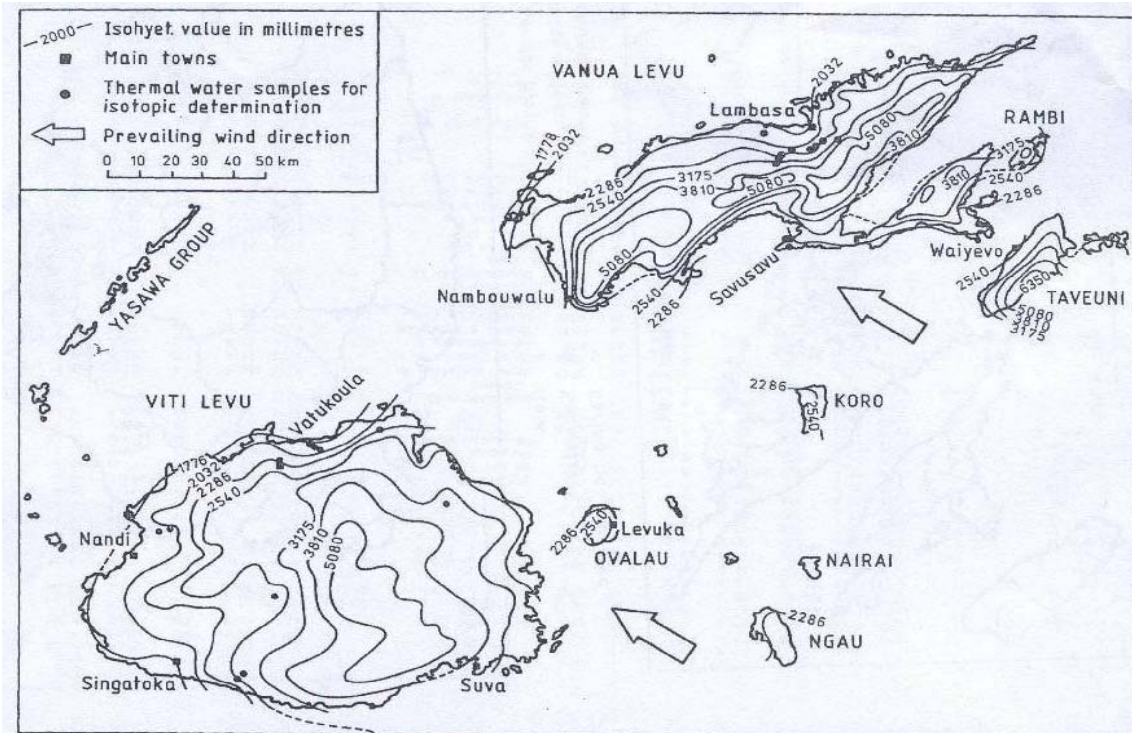

- incision and/or channelizing of landscape by the Sigatoka River;

- base-level responses of river systems and long-term interactions with relatively high relief causing hillslope processes and sediment generation;
- entrainment of sediments and debris to the ocean; and
- production of a suite of erosional and depositional landforms.

These roles are evident in the presence of temporary sediment storages and/or aggradation landforms around the reaches of the SR (Figures 1.2 & 1.5), including flood plains, abandoned river channels and terraces, and alluvial fans, which serve as geomorphic markers representing periods of abrupt climatic and/or environmental changes. Surface slumping, minor landslides and debris flows are ubiquitous in steep and dissected slopes, as manifested by vegetation-covered talus and scree.

1.3.3 Climate

Fiji's climate is classified as seasonal maritime tropical and is controlled by the Southeast (SE) trade winds (Figure 1.6) and seasonal movement of the Inter-tropical convergence zone and associated Hadley cells. This climate is characterized by a pronounced wet and dry seasons from November to April and from May to October, respectively (Gale & Booth, 1993). Up to 80% of the total annual rainfall falls during the wet season, also known as the cyclone season, with maximum rainfall always recorded from January to April (Cox & Hulston, 1980). The dry season is characterized by long (~25 sunshine days/month) dry spells with negligible precipitation. In addition to atmospheric circulation patterns, climate in Viti Levu is strongly influenced by the presence of several north-south mountain ranges (900-1400 m a.s.l) dividing the island into a humid windward (rainfall > 3000 mm y⁻¹) climate zone on the eastern side, and a dry climate zone on the west (rainfall < 2000 mm y⁻¹) (Waterloo, et. al., 1997) (Figure 1.6). The study area is located on the dry side, immediately adjacent to the transitional climatic zone (Figure 1.7), SW Viti Levu.

| Months | Jan | Feb | Mar | Apr | May | Jun | Jul | Aug | Sep | Oct | Nov | Dec |
|---------------------------------|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|
| Maximum temperature (°C) | 31 | 31 | 31 | 30 | 29 | 28 | 27 | 27 | 28 | 29 | 30 | 31 |
| Minimum temperature (°C) | 22 | 22 | 22 | 21 | 20 | 19 | 18 | 18 | 19 | 20 | 21 | 21 |
| Average rainfall (mm) | 277 | 253 | 295 | 182 | 106 | 74 | 77 | 73 | 99 | 102 | 142 | 189 |
| Number of days with rain | 16 | 16 | 17 | 13 | 10 | 7 | 8 | 7 | 8 | 8 | 10 | 13 |
| Daily sunshine (hours) | 5.5 | 5.1 | 4.8 | 4.7 | 5.2 | 4.7 | 5.2 | 5.9 | 5.4 | 6.1 | 6 | 6.2 |
| Monthly evapotranspiration (mm) | 156 | 136 | 127 | 105 | 89 | 73 | 76 | 97 | 112 | 139 | 148 | 158 |

Table 1.1: monthly climate data from Nacocolevu Agriculture Research Centre (Average for 1938-1982). Source: Hawaiian Agronomics International (1984).

The warmest period (Table 1.1), December to March, has a mean maximum temperature of 31 °C, with excess precipitation usually recorded and during which tropical cyclone season often occurs (Davies, 1992). The coolest period, July and August, experiences a mean maximum temperature of 27 °C (Gale & Booth, 1993). Davies (1992) added stated the SV experiences dry season between May and October, with little to no rainfall received during June and September and Table 1.1 shows this with an average monthly rainfall of 90 mm from May-October and around 220 mm during the wet or cyclone season. Potential evapotranspiration (PET) during the dry and wet seasons were recorded to be around 100 mm and 140 mm, respectively.

Figure 1.8: monthly average rainfall and PET obtained from Table 1.1 (average for 1938-1982) showing the distinct wet and dry seasons.

Clearly, net recharge is deficit during most of dry season due to high PET period, whilst excess water (i.e. surface and groundwater) is continued to be used and exploited for portable and irrigation purposes. This could threaten the long-term sustainability of water resources and hence, necessitates systematic and conventional investigation, procedures and mechanisms to ensure equitable allocation and sustainable groundwater management: some of which will be addressed in this research.

Figure 1.9: monthly rainfall averages recorded at Nacocolevu and Mavua rainfall stations for 1989-2009. Raw rainfall data and location map of the two climate stations in relation to the study area will be provided in Appendix A (Source: Fiji Metereological Service).

1.3.4 Soil, Vegetation and Land Use

Soil capping the study area has been classified by Rijkse (1990) as Sigatoka and Dubalevu series. The Sigatoka soil, occupying the Bilalevu area, are defined as very dark greyish brown to dark brown sticky, plastic, and friable silt derived from the recent alluvium comprising rocks of mixed mineralogy. The Dubalevu soil is characterized by very dark brown and yellowish brown, friable, slightly plastic and slightly sticky, silt loam derived from colluviums comprising sandstone of intermediate and basic composition (Rijkse, 1990). Vegetation cover varies spatially: the topographic highs are covered by grassland and scrub vegetation, together with thick patches of exotic pine trees and native species, whilst the topographic lows and alluvial flats are either covered with grassland or cultivated and thence occupied by human dwellings, such as villages or farm houses. From aerial photograph interpretation (API), thick and heavy vegetation tend to be concentrated around major water ways and river-valley bottoms. Landuse around the valley is controlled by semi-commercial farming whilst villagers are mostly engaged in subsistence farming. In semi-commercial farms, vegetable and root crops, including tomatoes, beans, beet, carrots, lettuce, cauliflower, cabbage, pumpkins, melons, pawpaw, and peanuts, pumpkin, cassava and corn farmers, are grown and harvested.

1.3.5 Population & Water Resources Use

The study area, together with neighboring villages and settlements, has experienced significant changes in population. An increase in the population of most villages had been recorded whilst population in Bilalevu and other farming settlements have decreased in the past two decades (Table 1.2): this may be ascribed to either rural-urban migration or non-renewal of land leases.

| LOCALITIES | POPULATION | | |
|----------------------|------------|---------|------|
| | 1986 | 1996 | 2007 |
| BILALEVU SETTLEMENT | 490 | 505 | 255 |
| DREKE VILLAGE | 104 | 124 | 159 |
| KORONISAGANA VILLAGE | 194 | 225 | 250 |
| MAVUA VILLAGE | 101 | 114 | 181 |
| NABITU SETTLEMENT | 388 | 427 | 380 |
| NARATA VILLAGE | No data | 129 | 156 |
| NAREWA VILLAGE | 205 | 205 | 237 |
| RARARUA VILLAGE | 142 | 200 | 170 |
| TOGA VILLAGE | 242 | 169 | 205 |
| VUNAREWA VILLAGE | No data | 123 | 143 |
| TUBAIRATA VILLAGE | No data | 65 | 144 |
| DUBALEVU SETTLEMENT | No data | No data | 31 |
| SIMILAYA SETT | 183 | 138 | 80 |
| NABAKA SETT | 417 | 267 | 157 |
| Total | 2466 | 2691 | 2548 |

Table 1.2 Population of villages and farming settlements within the study area (Source: Fiji Island Bureau of Statistics).

In response to such intensive landuse pattern and fluctuating population (Table 1.2), demand for water resources use is relatively high. A significant amount of surface and groundwater is utilized drinking and irrigation uses for human security and to ensure adequate water availability for optimum plant growth during the dry period. In Bilalevu, due to its close proximity to the SR, many farmers, through the assistance of the Ministry of Primary Industry's Agriculture Department, use low-lift engine-driven pumps for sprinkler irrigation scheme. Groundwater resources had been utilized for drinking purpose and marked by a growing number of 4" diameter privately drilled wells (PDW) around the study area in the last decade. The drilling of these wells were conducted by private drilling companies (PDC) and largely unknown to the MRD until the inception of this project. PDW are pumped at an average rate of 1 L/s for 4-8 hours daily: the details of these wells will be discussed in the next chapter. Dubalevu, having located relatively far from the Sigatoka River, utilizes groundwater for irrigation purpose with a few farmers opting to use these sources for

domestic use during severe dry periods. The SVRDP wells in Dubalevu have the maximum capacity of around 10-20 L/s (Gale & Booth, 1993) but are pumped at an average abstraction rate of 3 L/s. Settlements and villages located within and adjacent to the Dubalevu-Bilalevu corridor, namely Nabitu, Jubairata, Rararua and Laqere, also use groundwater for drinking and sanitation purpose whilst Mavua, Nasovatava, Vunarewa, Narewa and Toga are sustained by perennial streams catchments and spring sources (details of groundwater use in the study area will be discussed in later chapters relevant to the sustainable management of groundwater resources).

1.4 Outline of field investigation and methods

The investigation and characterization of the hydrogeological system around the MSV was conducted through the following methods:

- (1) satellite imagery and aerial photos (Appendix B shows a list if aerial photos used) were used during the reconnaissance stage to identify geomorphic, geological and structural features pertinent to the overall geological/tectonic setting, as well as the identification of subjective areas for geophysical surveys.
- (2) Global positioning system (GPS) surveys were used, through the use of Garmin76 device to capture location data of rock outcrops, geophysical survey lines, existing and newly installed boreholes, and chemistry and isotope sampling sites. These data were downloaded into MapSource software, and subsequently corrected and converted in formats compatible for GIS platforms, such as MapInfo 10.0.
- (3) Literature review was conducted on all existing and relevant geological, hydrogeological, landuse, climatic and isotope datasets available for the Fiji group, particularly the Sigatoka valley.
- (4) Engineering geological and geomorphic mapping and classification of surface outcrops, conducted by both vehicle and foot traverses, is conducted to establish of overall geological framework upon which groundwater exploration is guided.
- (5) Geophysical survey, using electrical resistivity and electromagnetic methods, is conducted on several sites to produce high resolution subsurface profiles showing variable geophysical properties upon which the selection of potential drill sites and determination of target depths are guided.

- (6) Soil permeability tests, through the “falling head method” and using the WF26010 permeameter cell, is conducted to determine the permeability of overlying fine material, namely silty loam, in relation to infiltrating meteoric and irrigation water into the groundwater systems;
- (7) Water resources inventory was designed, through interviewing owners and attendants of most privately drilled wells to determine the well depth, abstraction rate and duration of use on daily basis and number of families sustained by each of the groundwater sources, to establish the current status of groundwater use and to use as a tool for projecting groundwater or water resources sustainability in the long-term.
- (8) Groundwater drilling using mud-rotary method was conducted on 9 sites to permit the collection and assessment of drilled cuttings for lithological logs and proper construction materials were used to ensure strength and stability of groundwater wells and allow optimum water flow to be assessed for aquifer parameters calculations through pumping and recovery tests, respectively.
- (9) Pumping and recovery tests were conducted on several wells to permit the analysis and assessment of aquifer properties, namely transmissivity, storativity and hydraulic conductivity, as well as to allow the collection of groundwater samples for chemical and isotope analysis.
- (10) Groundwater levels of existing wells were also measured using a SOLINIST dipper on two occasions to determine the direction of groundwater flow around the Dubalevu and Bilalevu area
- (11) Groundwater chemical sampling on existing groundwater wells and on surface water sources, namely creeks, river and springs, in Dubalevu, Nabitu, Nabaka, Similaya and Bilalevu and the analysis of major ionic compositions, total dissolved solutes (TDS) to determine the dominant hydro-chemical facies and any spatial variability.
- (12) Isotope sampling and analysis on numerous water sources, namely groundwater wells, creeks, and rivers, was conducted through the mass fractionation of H^1/O^{16} and H^2/O^{18} to establish the abundant isotopic composition and determine if groundwater is derived from either rapidly through flowing rain-derived recharge or dispersed slowly through fractured bedrock areal sources.

(13) Chloride concentration test was also conducted on the isotope samples using the Orbecco-Hellige 975 analyst.

The selection of above methods was primarily controlled by:

- funding availability from government for logistical support, preliminary groundwater chemical analysis, groundwater investigation, groundwater drilling and development, procurement of borehole construction materials and arrangement for suitable pump sizes. Please note that several other pre-planned investigation methods, such as river gauging, pesticide residues analysis in groundwater, and groundwater dating, were not conducted due to financial constraint;
- availability of suitable equipment such as geophysical instrument, permeater, drilling rig, drilling mud and groundwater pumps;
- availability of facilities for chemical analyses at MRD's Geo-chemical Laboratory and isotope analysis at the University of Canterbury; and
- time constraint – A period of 16 months was initially allocated for the completion of this research project and during which all data acquisition through the above-mentioned methods, interpretation and documentation were to be completed. Extensions were granted by the College of Science due to exceptional circumstances, such as several tropical cyclones in Fiji between November, 2009-January, 2010, project breakdowns, funding disbursement delays, delayed student visa renewal procedures in Fiji and, finally, the devastating February 22nd Christchurch earthquake.

1.5 Thesis Organization

The thesis is organized such that:

- chapter 1 provides the project background and primary objectives of this thesis before describing the study area in terms of location, geology, physiography, climate, vegetation and landuse with an introduction to the investigation methods employed for this hydrogeological study,
- chapter 2 presents the literature review of geological and tectonic setting of Fiji with their relevance to the hydrogeological and geomorphic systems in the study area before providing an overview of the hydrogeological system based on the SVRDP.

This reviews the groundwater utilization in Fiji, the status of groundwater policies and legislations before isotope hydrology will be reviewed including previous isotopic survey conducted in Fiji,

- chapter 3 provides field investigation methods and results of geophysical surveys, geological and engineering geological mapping, pumping tests and, groundwater exploration drilling, chemistry and isotope sampling, chloride concentration tests and groundwater recharge calculations,
- chapter 4 provides discussions for geophysics, physical hydrogeology, hydrochemistry and groundwater recharge,
- chapter 5 examines issues and challenges encountered during this research before providing a series of recommendations for groundwater sustainable management, and
- chapter 6 provides the major conclusions of this thesis and outlines areas of further study.

Chapter 2: Literature Review

2.0` Introduction

This chapter presents existing geological, hydrogeological surveys around the SW Viti Levu, as well as relevant water resources studies around Fiji to aid the characterization of the hydrogeological system in question. The chapter is organized to first cover both regional geological and tectonic evolution of southwest Viti Levu, Fiji. This is followed by a review of eustatic/sea level fluctuation records in the Pacific and in Fiji in relation to the deposition of Quarternary and Recent Alluvium before an overview of geological setting of the study area is provided. These are followed by the snapshot of groundwater utilization around Fiji, including progresses and history of groundwater development in Fiji, the hydrogeological setting of the study area as per the Sigatoka Valley Rural Development Project (SVRDP), as well as an overview of the current groundwater utilization in the study area. These are followed by an overview of groundwater policies and legislation before concluding with an introduction to isotope hydrology and results from previous isotopic studies in Fiji.

2.1 Regional geology and tectonic evolution

The Fiji Islands, in the southwest Pacific region, are located between the Pacific and Indo-Australian tectonic plates boundary and sits on a broad, shallow submarine platform close to the ocean deeps delineating the western edge of the Pacific Plates (Hamburger, 1986) (Fig. 2.1.1). Hence, the geological framework, documented in Hamburger (1986), Rodda (1994) and Hathway & Colley (1994), Webb (1999), Rahiman (2006), is dominated by remnants of arc-related volcanic, plutonic rocks with repeated sequences of volcanoclastics sediments as attributed various stages of island arc development. Further, recent phases of magmatism are related to arc fragmentation and rifting in neighboring back-arc basins whilst periods of tectonic quiescence and instances of sea-level fluctuation, are recorded in development of numerous sedimentary basins and deposition of fluvial materials, respectively.

Figure 2.1: regional tectonic setting (Hamburger, 1986).

2.2 Geological and tectonic setting – Fiji

The islands of Fiji comprise of Late Eocene to Recent predominantly plutonic, volcanic, volcanoclastic facies, with sedimentary rocks forming in numerous depositional basin (including a few raised Holocene Limestone islands), together with recent alluvial materials (Gale & Booth, 1993). The oldest dated rock being the Yavuna stock is dated around 40-36 Ma, is found to be outcropping SE of Nadi in Viti Levu, whilst the most recent volcanic eruption occurred approximately 2000 years BP on Taveuni. This timescale included numerous proto-volcanism and sedimentation events, synchronous deformation episodes and neo-volcanism. This next sections will focus on Late Eocene to Late Miocene tectonics event and geological groups concentrated on SW Viti Levu, namely the Yavuna Group, Wainimala Group, Colo Plutonic Group, and Tuva Sedimentary Group: details of Fiji's geology are provided in Rodda (1994), Rahiman (2006) and Hathway and Colley (1994).

2.2.1 Yavuna Group (YG)

The YG is viewed as a proto-volcanic-arc formed following the inception of convergence between the Pacific and Indo-Australian plates in the Eocene (Hathway & Colley, 1994) and

was spanning between Late Eocene and Oligocene (Figure 2.1.2). The group, Fiji's oldest rocks and among the oldest observed in the Southwest Pacific Islands (Hamburger, 1986), has major occurrence outcrop southwest Viti Levu (Figures. 2.2 & 2.3) and is composed of primitive and dominant arc-like dacitic rocks, shallow-water limestone, a tonalite/trondhjemite stock with basaltic pillow lavas (Rodda, 1994). The Yavuna Stock, accepted to be located in the West of the convergence regime, marked last magmatic orogeny in the remnant-arc before the opening of the South Fiji Basin in the Late Oligocene (Figure. 2.5) and prior to its northeastward rift and migration (i.e. 36-25 Ma (Rodda, 1994)).

Figure 2.2: southwestern Viti Levu location and distribution of the Yavuna Group ((Rodda, 1994).

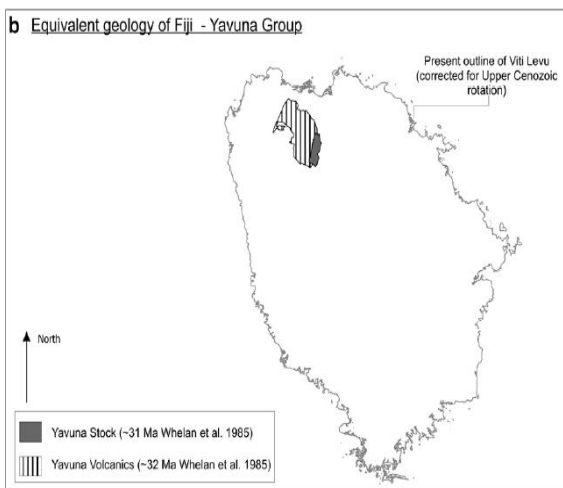

Figure 2.3: possible location and orientation of the Yavuna Group and Viti Levu on the proto-arc (Rahiman, 2006).

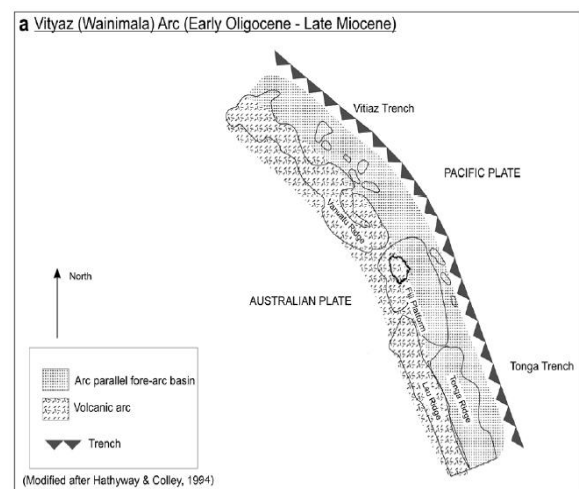

Figure 2.4: Proto-arc and the continuous Vitiyaz arc, the Melanesian arc (Rahiman, 2006).

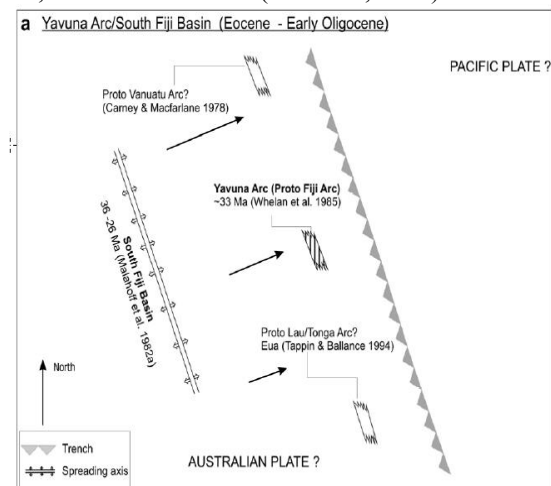

Figure 2.5: Opening of the South Fiji Basin marking the onset of Wainimala arc (Rahiman, 2006).

This opening of the South Fiji Basin (Figure 2.5) was accompanied by swarming of dolerite dyke intrusion with periods of uplift and normal faulting. Following these, southwest and westward directed subduction of the Pacific plate under the Australian plate instigated a

period of volcanic activity along the rifted southwestward margin of the Yavuna Block and resulting in the development a new volcanic arc comprising the Waimala Group (Figure 2.4). During this period, the proto-arc (also known as Melanesian arc) was composed of the ancestral Solomon, Vanuatu, Fiji Platform (FP)/Lau, Tonga and Kermadec-Colville arc segments along the Tonga-Kermadec Trench and the now relict Vityas Trench: this marks sites of former subduction zone (Hamburger, 1986) and lying north of Fiji's present position (Rahiman, 2006) (Figure 2.3).

2.2.2 Wainimala Group (WG)

The WG, constituting a fore-arc basinal and arc assemblage (Rodda, 1994), was unconformably formed on the proto-arc basement (i.e. angular unconformity) with the youngest magmatic rock range from 10 to 14 Ma (Rahiman, 2006). During this period (Up until the middle-Late Miocene), the Melanesian arc prevailed (Hamburger, 1986) with the Pacific Plated being subducted from the east along the Tonga-Vitiaz trench (Webb, 1999). The submarine rocks of the group (predominantly found in the western and eastern part of Fiji), consist of intrusive and extrusive basic to acidic lava flows (dacite, basalt and andesite) some of which were later deformed by greenschist facies regional metamorphism (Rodda, 1994), fragmental rocks (volcanic breccia and conglomerate), argillites and pelagic limestone.

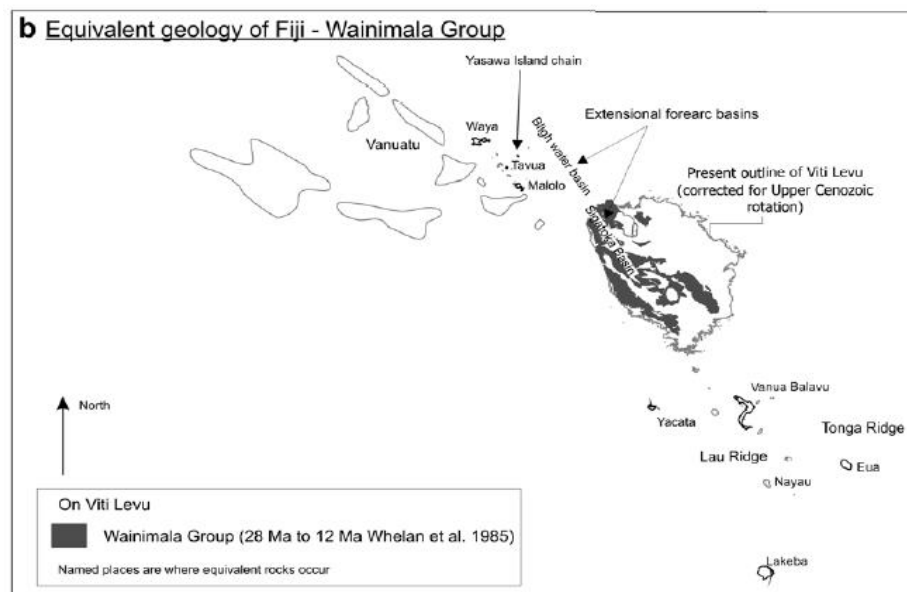

Figure 2.6: position of ancestral forearc-intraarc Sigatoka Basin and the Bligh Water Basin during the formation of the Wainimala Arc.

The basinal assemblage in this Wainimala arc was interpreted to be deposited in a fault-controlled (half-graben) fore-arc and intra-arc Sigatoka basin, composed of an uplifted Wainimala arc block from a downthrown (hanging wall) Yavuna block on the north (Hathway & Colley, 1994): these were related to the crustal thinning and extension related to the opening of the South Fiji Basin. Webb (1999) documented that the southern (arcward) migration of the former depositional environment and the formation of Early Miocene to Middle Miocene Limestone can be attributed to emergence as a result of isostatic uplift due to crustal thickening in the accretionary wedge and under-plating, which could have resulted in the erosion of Wainimala arc and associated reef/platforms. Further, the deposition of carbonate coincided with an increase in epiclastic sediment yield to the forearc, indicating increased emergence, which brought larger submerged areas into the photic zone, and erosion of the arc (Hathway, 1995). Of the numerous Wainimala Group members, the Tari Formation and Qalimare Limestone are of special interest due to their existence in the study areas.

2.2.3 Colo Plutonic Group (CPG)

This plutonic group or suite occur in an elongate belt from southwest Viti Levu with compositions ranging from olivine-augite gabbro through quartz gabbro to tonatite (Rodda, 1994) and Rahiman (2006) summarized several events during this period including:

- widespread plutonism occurring in an elongated E-W belt southern Viti Levu from 12-7 Ma, referred to as the Colo Plutonic Suite – the Colo Orogeny, and
- brittle and ductile deformation, with the formation of anticlinorium encapsulating the plutonic belt (Figures 2.7 & 2.8) and deformation in rocks post dating the Colo Orogeny, notably those on the Tuva Group in southwest Viti Levu.

These plutonic intrusions and associated deformations and volcanic eruption episodes marked the break-up and/or fragmentation of the ancient Melanesian arc into series of ridge and arc systems during the Middle to Late Miocene. Having concentrated around the SW Viti Levu, this orogeny is responsible to widespread contact metamorphism around the area, particularly the WG.

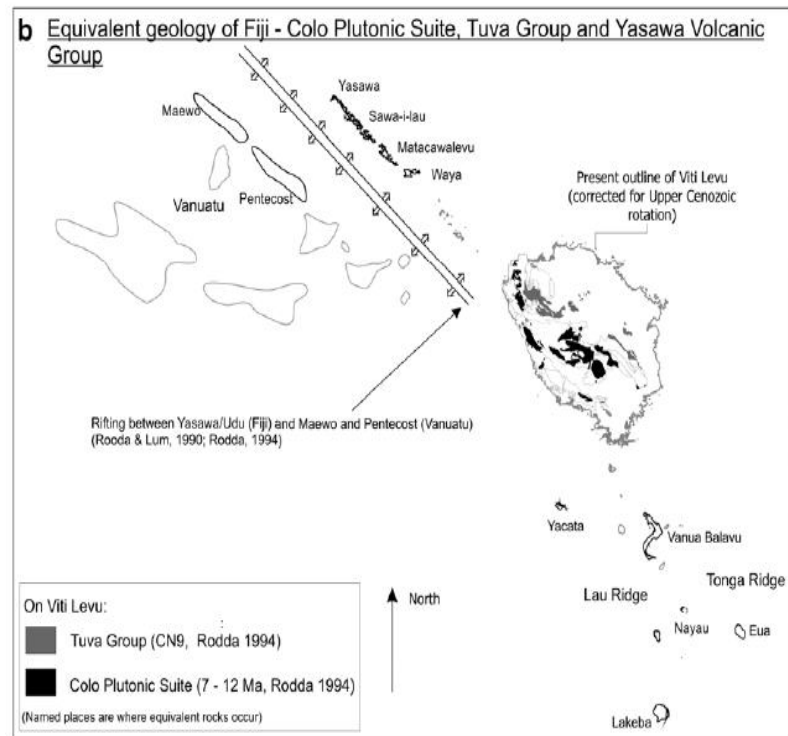

Figure 2.7: location of Colo Plutonic suite and younger units prior to rotation (Rahiman, 2006).

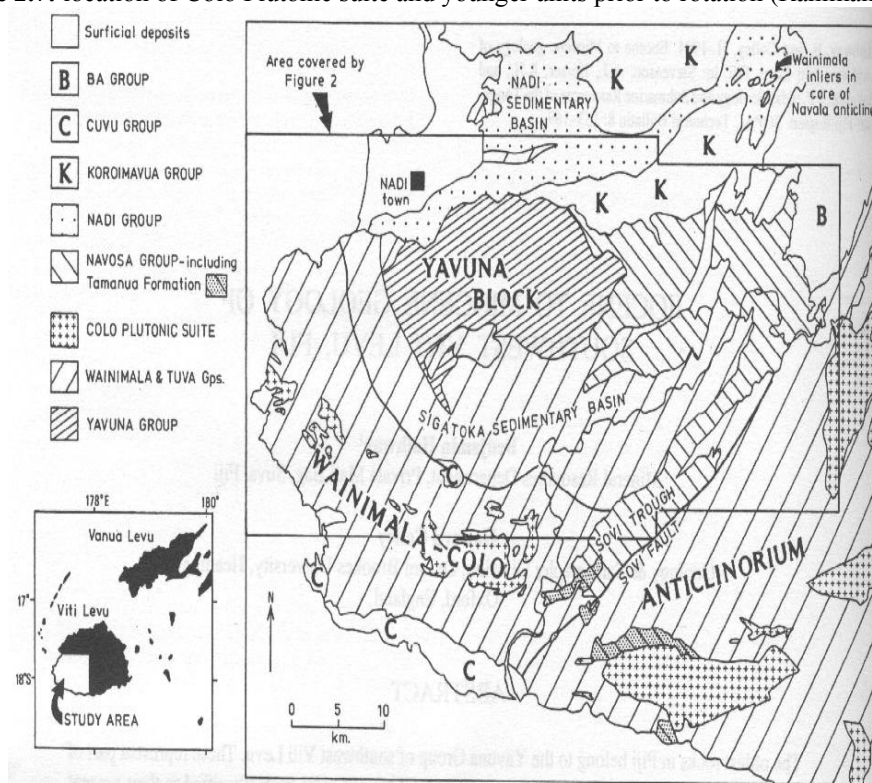

Figure 2.8: distribution of Wainimala Group, orientation of anticlinorium on Southwest Viti Levu (Hathway & Colley, 1994).

2.2.4 Tuva Sedimentary Group (TSG)

This middle to late Miocene and post-Colo Plutonic sedimentary group is composed of as breccias, conglomerate and sandstone with minor mudstone, strongly deformed in places and comprising the Cici Sandstone and the Takaro Conglomerate (Rodda, 1994). Hathway (1989) defined the latter as a poorly sorted weathered-unweathered matrix-supported rudite in which well-rounded to angular clasts of andesite, dacite and limestone are locked, whereas the former was defined a feldspathic lithiarinites with a conservative thickness estimate of 600m. The Tuva Group have been construed as a turbidite system in the fault-controlled the Wainimala arc. The arc's adjoining basin, the Sigatoka Basin, with its half-graben correlatives in the Tonga platform (Oligocene-Miocene in age), have been subject to several phases of normal faulting, which creating sufficient space to accommodate the deposition of minor volcanoclastic rudites, sandstone, and siltstone and hence, prevented the formation hemipelagic carbonates (Webb, 1999). The sedimentary group, having an extensive coverage on the study area, will be described further in later chapters.

2.2.5 Disruption or fragmentation of Melanesia Arc

Subduction along the Vityas arc ended as a result of collisions with Pacific plate oceanic plateau whilst the Melanesian Border Plateau collided north of Fiji with the Ontong-Java Plateau, further north near the Solomon Islands (Rahiman, 2006) and hence, the commencement of the fragmentation of Melanesian arc around the Middle-Late Miocene (Figure 2.9). This resulted to the fragmented configuration seen today, which requires separation of Vanuatu and Fiji in the western sector and polarity reversal, as well as drifting away of the Vanuatu arc segment from Fiji. Subduction polarity reversal on the Vanuatu arc resulted from continued subduction between Australian plate and Pacific Plate, whilst breakup of Melanesian arc and rifting led to opening of the North Fiji Basin (NFB).

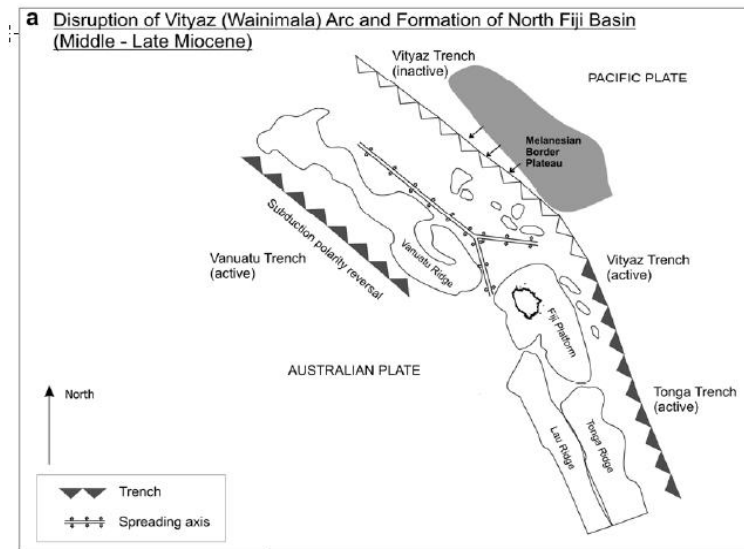

Figure 2.9: initial breakup of Melanesian arc (Rahiman, 2006).

During the fragmentation, the FP may have gone through a 30-40° anticlockwise rotation between 5.5-2.5 Ma (Webb, 1999) and during which crustal compression and shortening occurred with the emergence of the Yasawa Island group: this is clearly observed by the deformed Wainimala and Tuva Group group in SW Viti Levu. Malahoff (et.al, 1981) added that paleomagnetic analysis conducted on fifteen oriented rock samples from the Ba Volcanic Group showed an age of 2.9-7 Ma as evidences of post-Miocene rotation of the island of Viti Levu.

2.3 Records of climate change and eustatic fluctuation

2.3.1 Introduction

Relative sea level (RSL) are a product of changes in oceanic and crustal variables, which depend on sea surface level changes, any isostatic, glacial and tectonic changes and local coastal processes (Woodroffe & Horton (2004)). The Pacific islands have been subject to these events overtime where RSL fluctuated to which hydro-isostasy, localized and regional tectonism (i.e. forearc and backarc processes), and universal glacio-eustatic fluctuations have been attributed (Dickinson, 2001).

2.3.2 Global and regional events

The last oscillation between glacial and interglacial conditions during the Quaternary, the Last Glacial Maximum (LGM) (between 30000 and 19000 years ago) transferred millions of ice in the ocean and hence, global sea level in regions, particularly in far-field locations, rose by about 130 m (Woodroffe & Horton, 2004). Thus, the return of ocean waters to the glaciations centres during the interglaciation period led to the drastic sea level drawdown. These events were also imprinted in the relatively young Pacific where terraces in the islands of Tongatapu and Eua in Tonga, which are dated back to this inter-glacial event (Dickinson, 2001). However, a substantial portion of Pacific region was still undergoing tectonic moments over Holocene, and even longer timescale, and RSL fluctuation was attributed to geoid migration (Woodroffe & Horton, 2004). During the mid-Holocene, sea level may have risen 2.1m above present 4200 cal yr BP before gradually falling to present level (Kumar, 2006). Evidences of this Holocene high sea-level stand in Vanua Levu, including the presence of higher paleonotch observed around the southeastern coast were 2.2-3.3 m above low-tide level and lower paleonotch 1.5-1.6 m above low-tide level which with encrusting corals were dated to be 6000-3400 yr before present, confirmed sea level was higher than at present (Miyata et.al., 1990). Dickinson (2001) added that paleo-shorelines in coastal areas of Viti Levu was characterized by rising paleo-beach rock (mid-Holocene age of 4000 yr BP) rising to an elevation 1.4 m above modern and with coastal beaches cut into uplifted Quaternary reef flat limestone at elevation of 1.8-2.2 m above modern shoreline notches. These fluctuations in paleoshoreline would have significant impacts in paleo-fluvial processes via the advancement and recession of base level, which in turn dictate their tendency to either degrade or aggrade the river beds.

2.3.3 Relevance to the study area

Seismic reflection survey conducted around the Sigatoka River and Navua River produced profiles construed as alluvium materials infilling deeply steeply incised country rock or bedrock and signifying low sea level between 100 to 130 m below present day sea level (Figure 2.10) (Smith, 1989).

Figure 2.10: deeply incised country rock (Tari Formation) in response to interglaciation after the LGM (Smith, 1989).

Davies (1992), based on geophysical surveys and lithological samples of groundwater exploration drilling around the Sigatoka valley, commented that the alluvium deposits around the valley were episodically built above bedrock post-LGM, which was deeply incised by Sigatoka River bedrock 18 000 yr BP and during which much of the ocean was returned to the glaciations centres after LGM resulting in a massive sea level drawdown (Figure 2.11).

Figure 2.11: longitudinal profile of the Sigatoka River (Davies, 1992).

Again, the inception of RSL transgression post-LGM, as mentioned earlier, coupled with numerous localized paleoshoreline fluctuations from Quaternary to Recent, control the deposition and aggradation of fluvial materials along the Sigatoka River.

2.4 Geological setting of the study area

The study area is underlain by the steeply inclined and deformed Wainimala arc basinal/sedimentary group and the juxtaposed Tuva sedimentary group, with the incised valleys filled with Quaternary to Recent Alluvium deposits. Clearly, the evolution of tectonic systems controlling arc volcanism and basinal environment with episodic sedimentation and carbonate deposition together with Holocene eustatic fluctuation has dictated the deposition and formation of such a geological framework. Further, the compression and deformation instigated by the fragmentation of proto-Melanesia arc and the ensuing anti-clockwise rotation of the FP is evident in the ENE-WSW sinistral Nasovatava Fault (NF). These will be covered in detail in the next chapter.

2.5 Groundwater development & utilisation in Fiji

The following sections present the status of groundwater use and development in Fiji. This includes a history of groundwater development in Fiji and an overview of groundwater use in Fiji. These are followed by a view of the hydrogeological setting of the SV area as per the Sigatoka Valley Rural Development Project (SVRDP) results before groundwater utilization in the study area is discussed.

2.5.1 History of groundwater development, use and monitoring in Fiji

The Mineral Resources Department (MRD) and its predecessor, the Geological Survey Department (GSD), committed to a program of groundwater exploration, assessment and development since 1967 (Peach, 1988). Despite the lack of professional staffs and appropriate technology, MRD maintained its interest in groundwater development and, has since, conducted groundwater assessment and development with its own funds, together with PWD funds and

foreign aids. In 1985, the groundwater resources assessment and development unit (GRADU) was formed and operated to systematically assessing and developing groundwater resources to allow the continued development of the people of Fiji (Peach, 1988). Further, groundwater monitoring network was established by the GRADU as funded by the British Government (1985-1990), SVRDP (1988-1991) and the Japanese Government funded North Viti Levu groundwater development project (1993-1995), where places like Yaqara, in Tavua, Vatiyaka in Ba were investigated. The Hydrology section of the Public Works Department provided funds for the installation of groundwater wells in northern and western Viti Levu whilst French Government aid project permitted the installation of numerous well in Seaqaqa, Bua and Labasa in Vanua Levu (Kumar, 1997). These resulted in the compilation of 1:250 000 Hydrogeological maps of Viti Levu and Vanua Levu and Taveuni and are described in Gale and Booth (1993). At present, despite financial challenges, groundwater monitoring is still conducted, on monthly and quarterly basis, in several wells in Dubalevu, Korotogo, Namaka, Tavarau, Yaqara, Rabulu Viti Levu and Vanua Levu (Figure 2.12).

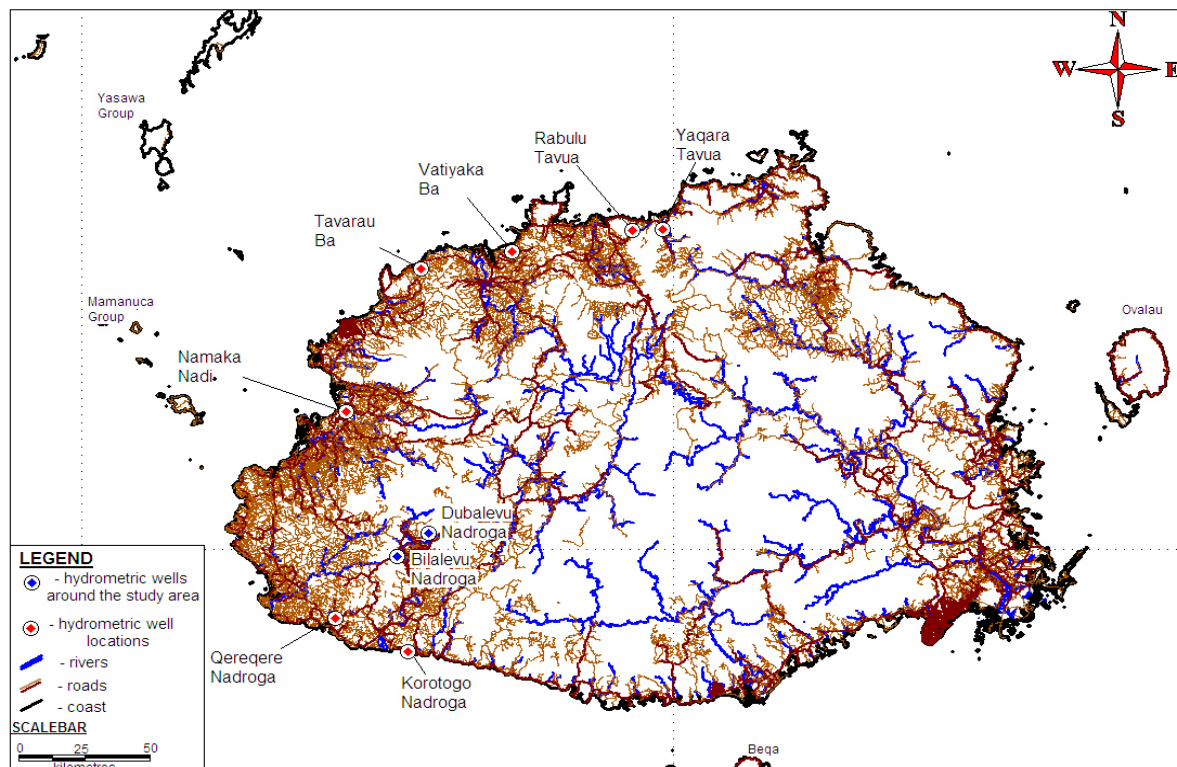

Figure 2.12: boreholes around SW and NE Viti Levu that are monitored on monthly and quarterly basis.

2.5.2 Overview of groundwater demand and use

In response to the rapid population growth and frequent extreme climatic events, particularly droughts, groundwater development projects for public water supply in Fiji had grown recently. , Government funded groundwater exploration and development, through the GRADU's annual budget allocation, has extended to villages, communities and schools on the two main islands in Fiji, as well as small islands, mainly for drinking purposes. This trend is likely to escalate in the long-term due to the frequent water-shortages and possible contamination of existing surface sources from improper landuse practices. Further, several groundwater private drilling companies (PDC) are in operation in Fiji and are responsible for the provision of groundwater sources for small community and individual-household water projects, most of which are unknown to MRD. Simultaneously, the success of "Fiji Water Brand" in the commercial bottling arena has attracted potential foreign investor to establish commercial bottling ventures and at present 4 bottling companies in operation in Viti Levu. However, MRD, being custodian of all minerals in Fiji, as stipulated in the Mining Act, have assumed control over the exploration and development of groundwater resources and have been given the mandate to provide relevant policies.

2.5.4 Hydrogeological setting of the study area

As mentioned earlier (section 1.1), the rural development project in the Sigatoka valley (SVRDP) was intended to upgrade the agricultural sector through the provision of reliable of irrigation sources, particularly during the dry season. Low-lift pump method, initially proposed to abstract water from the SR at an average rate of 9 L/s (Mr Govin Raju, Senior Agricultural Officer, Nacocolevu Agriculture Office, Sigatoka, pers.comm, April, 2010), was favoured due to its mobility. Such a distribution system will be a success to areas located within 400 m of river-bank abstraction point but a substantial portion of the targeted farmland were located beyond this distance (Figure 2.13). Hence, alluvial groundwater sources were proposed and to which a special requirement was made to permit wells having yields above 8 L/s to be constructed for irrigation purpose.

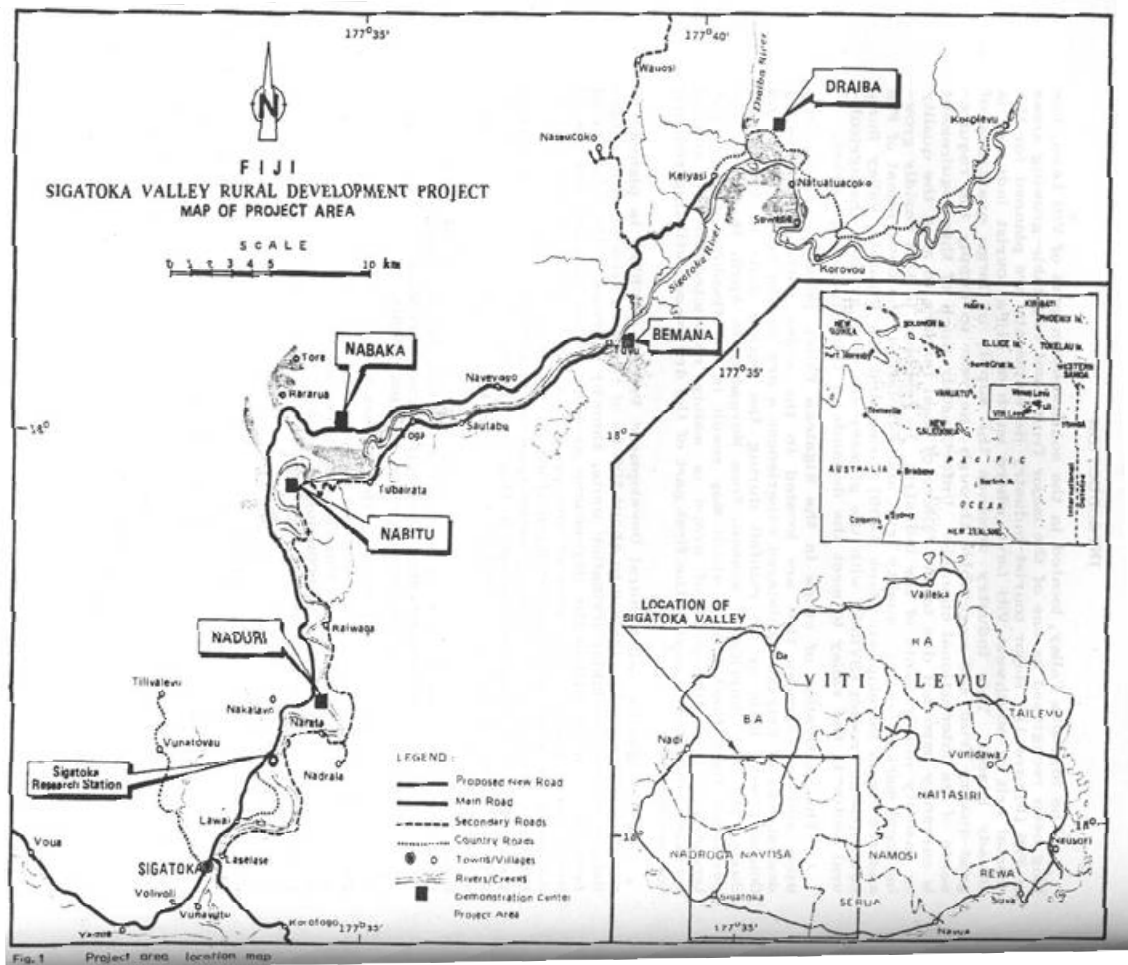

Figure 2.13: Farming areas identified as ideal for groundwater exploration (Davies, 1992).

Groundwater investigation, conducted by MRD, entailing geological, geomorphological and geophysical surveys on six identified areas, namely Draiba, Dubalevu, Nabaka, Nabitu, Bilalevu and Naduri (Figures 2.13 and 2.14), to assess the nature and groundwater potential of the alluvium deposits in the valley for irrigation purpose. Summaries and locations of the drilled wells are provided below:

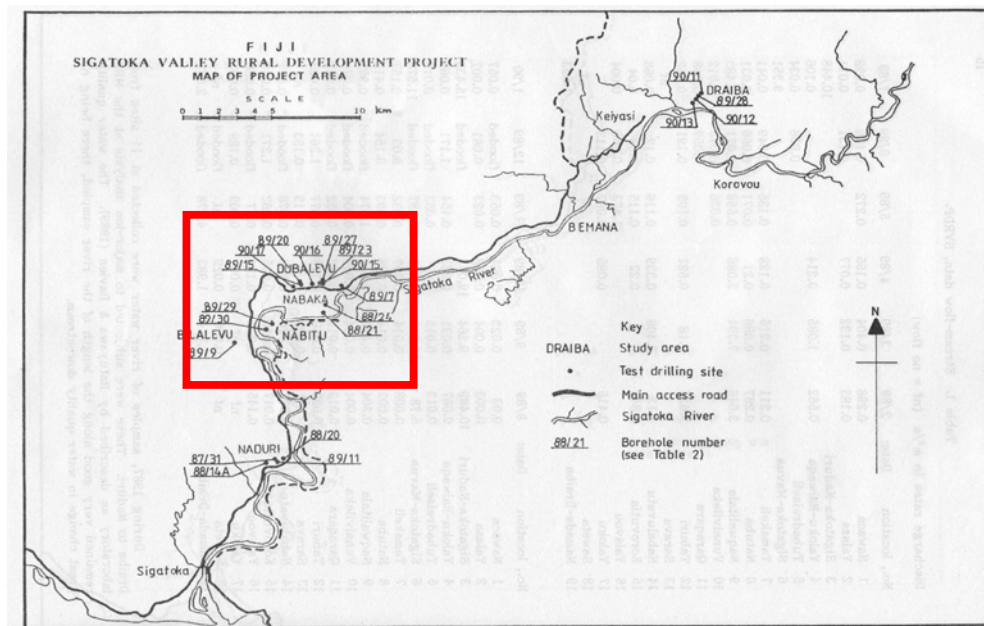

Figure 2.14: location map of wells drilled during the SVRDP project (study area denoted by the red square) (Davies, 1992).

Figure 2.15: location of SVRDP exploration wells around the study area.

Figure 2.16: tentative model of sediment deposition following bedrock incision in response to eustatic fluctuation and as consequent, the SR may have shifted on numerous occasions, hence, deposition and distribution of unconsolidated gravels will vary over space (Davies, 1992).

The project was concluded with the drilling and evaluation of 21 exploration groundwater wells and 7 of which (Dubalevu (4), Naduri (1), Draiba (2)) meeting irrigation scheme requirement (Table 2.1). As per project intention, the hydrogeological classification of the valley was dominated by QRA deposits, comprising unconsolidated coarse gravels and fan outwash gravels, medium to coarse sands with minor silt, which were unevenly distributed as controlled by episodic migration of the Sigatoka River (Figure 2.16). The underlying Wainimala, Tuva and Navosa Sedimentary Groups were deemed low productivity systems, whilst the WSW-ENE sinistral fault zone investigation at Bilalevu was inconclusive as borehole 89/9 recorded negligible yield (Figure 2.15 and Table 2.1). Further, it was recommended that the QRA aquifer systems show potential for water supply development for domestic needs, to the benefit of all rural communities within the Sigatoka valley (Davies, 1992)

| Location | Naduri | Bilalevu | Nabitu | Nabaka | Dubalevu | Draiba |
|-------------------------------------|--|---|---|--|---|---|
| Number of exploration wells drilled | 4 | 1 | 2 | 2 | 8 | 4 |

Table 2.1: summary of SVRDP exploration wells and hydrogeological characteristics with the main aquifer investigated include Quaternary-Recent Alluvium (QRA), Tuva Sedimentary Group (TSG), Wainimala Group (WG) and Navosa Sedimentary Group (NSG) (Davies, 1992).

2.5.5 Intensification of groundwater use/exploitation - the study area

As mentioned above, several of wells were drilled in the Dubalevu, Nabaka, Nabitu and Bilalevu area (Figure 2.15). Four wells in Dubalevu were deemed favourable for the irrigation scheme and are currently in operation for sprinkler irrigation system, while farmers are forced to also use these wells for domestic use during prolonged dry seasons (the other wells around the Dubalevu area were continuously monitored in the above-mentioned hydrometric scheme (Section 2.5.1)). Wells 88/24 and 89/29 located in Nabaka and Nabitu, respectively, are currently used for domestic water supply by Mr Janmin Jai and Mr Anil Prasad, respectively, whilst the other SVRD wells were abandoned due to either low yield or poor water quality (Figure 2.17). To date, farmers in the Bilalevu, Nabitu and Nabaka are using the mobile low lift-pumps to operate the sprinkler irrigation system, which utilizes the Sigatoka River (Figures 2.18-2.21).

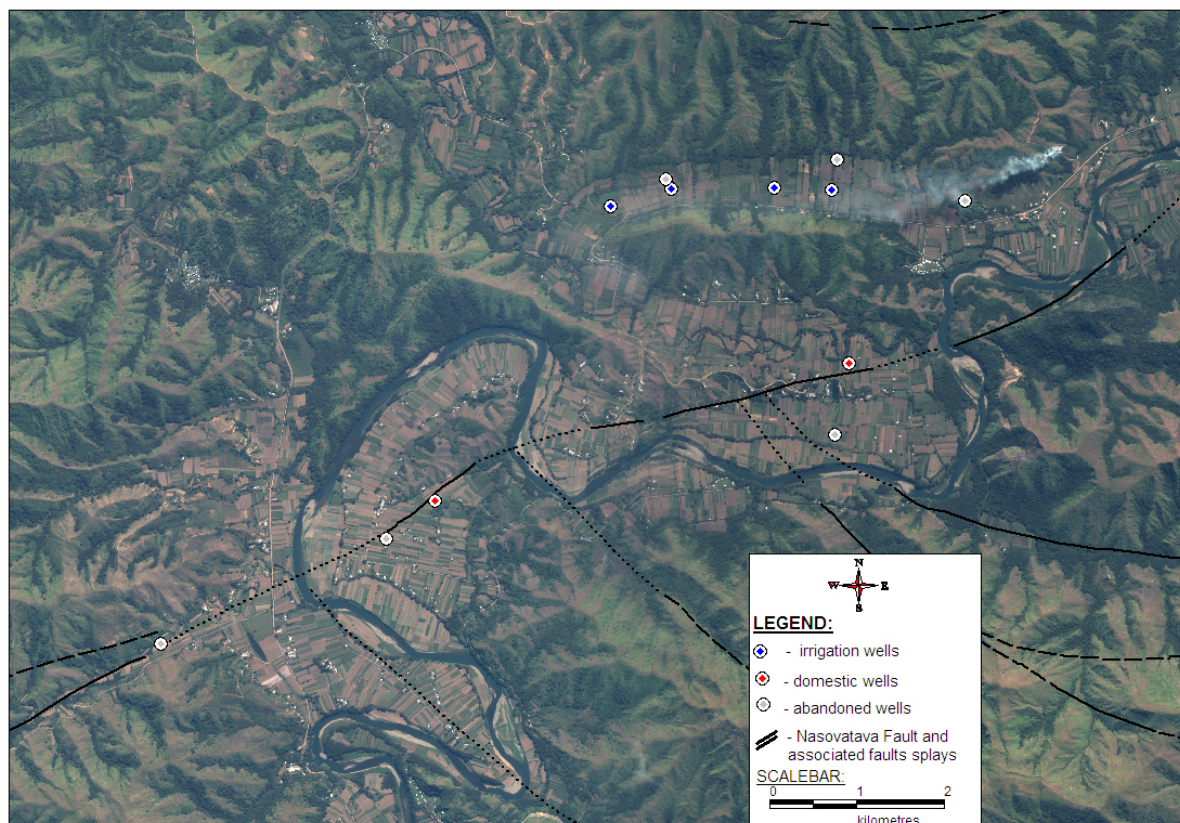

Figure 2.17: location of SVRDP wells within the study areas: irrigation wells, wells now used for domestic water supply and abandoned wells.

Figure 2.18: low-lift pump abstracting water from the Sigatoka River at 9 L/s.

Figure 2.20: irrigation water abstracted from SR and distributed to farmers through polythene hose.

Figure 2.19: Sprinkler-irrigation scheme operating in Bilalevu.

Figure 2.21: Sprinkler system used in an egg plant field in Bilalevu.

Following the success of the SVRDP, a number of privately drilled wells (PDW) were installed in the Bilalevu area. The continual growth in farming community and extreme climatic conditions, such the 1998 drought event, resulted in the accelerated groundwater exploration demand for community and domestic water supply. Consequently, approximately 25 wells, all of which are 4 “ in diameter and drilled by private drilling companies, namely Nagan Drilling and Western Drilling, have been drilled within the study area.

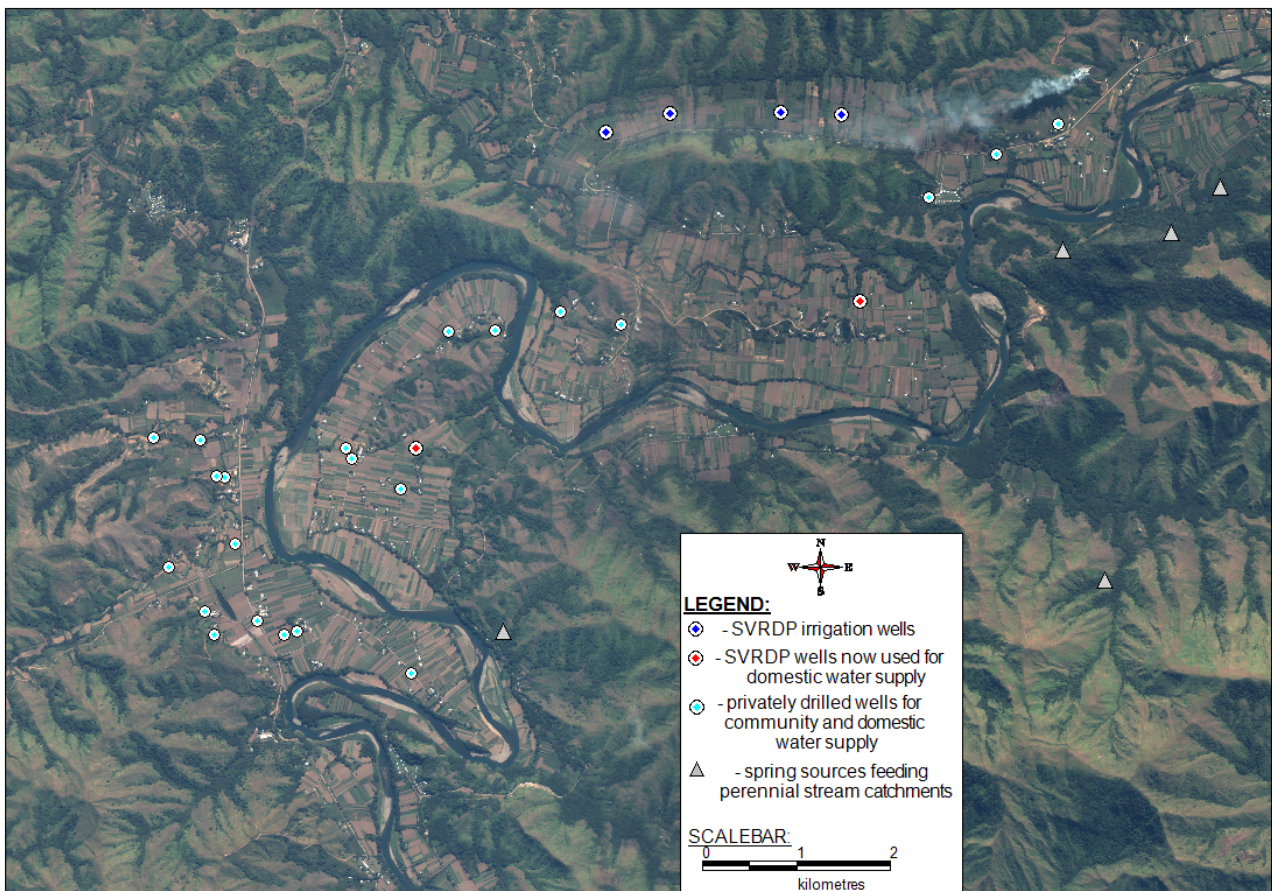

Figure 2.22: existing SVRDP and private wells, as well as springs around the study area as of November, 2010.

Most of these private wells, drilled for community water projects, have been co-funded by the Ministry of Multi-Ethnic Affairs (MMEA), whilst some are funded and owned by individual households (Figure 2.22). These private wells were drilled without the knowledge of MRD and attempts to obtain well logs from private companies proved futile. Several adjacent villages, namely Jubairata and Rararua utilize private wells for drinking purposes, whereas Toga, Vunarewa, Dreke, Narewa and Narata, utilize the

springs and perennial stream-catchments for portable purposes (Figure 2.22). These springs and stream catchments, occurring in the highly fractured local sedimentary units, are sites of groundwater discharge and hence, signifies the intensification of groundwater use in the area, as well as demonstrating the hydrogeological potential of the underlying basement. Details of current groundwater abstraction rates of these private wells, depths and groundwater use will be covered in later chapters in relation to groundwater recharge estimation.

2.6 Status of groundwater policies & legislation

The FG neither has a policy nor a legislation to warrant the sound protection and sustainable management of groundwater resources. Peach (1988) enumerated several longstanding issues (and still prevalent today) hampering the progress of groundwater development and management in Fiji such as:

- no clear, coordinated national water policy culminating in the uncoordinated efforts of many different agencies, government and private, in the attempt to develop water resources, and
- absence of groundwater legislation meaning that there can be no effective conservative of groundwater and protection of the resource from improper and unsustainable use.

2.6.1 Existing water legislations

To date, there are numerous existing legislations that deal with various aspects of surface water and **NO** legal reference to groundwater. These existing legislations, including the River and Streams Act, Mining Act, Irrigation Act, Water Supply Act and Environment Management Act, have varying roles and controls in the utilization, allocation and management of surface water resources, with minor emphasis on groundwater quality management in response to mining activities. The Fiji Government has, recently, taken numerous steps towards the formulation and enactment of groundwater legislation. In August, 2002 at a preparatory meeting to the Kyoto 3rd World Water Forum, Pacific Island leaders agreed to a Pacific Regional Plan on Sustainable Water Management so as to strengthen their commitment to the 2001 United Nations Millennium Goal. Subsequently, the FG initiated the design, development and documentation of the “Fiji Islands Water Policy”: this responsibility was handed to the MRD and is currently in draft stage (Rao & Dau, 2004). This policy recognized that prior to 1874, ownership of land

and water resources in Fiji was vested with tribal chiefs. This ownership, currently having two different legal opinions (Figure 2.23), was affected when chiefs ceded Fiji to Her Majesty Queen Victoria in October, 1874, which permit the colonial administration make laws that transferred the control of land and other resources from local control (Rao & Dau, 2004).

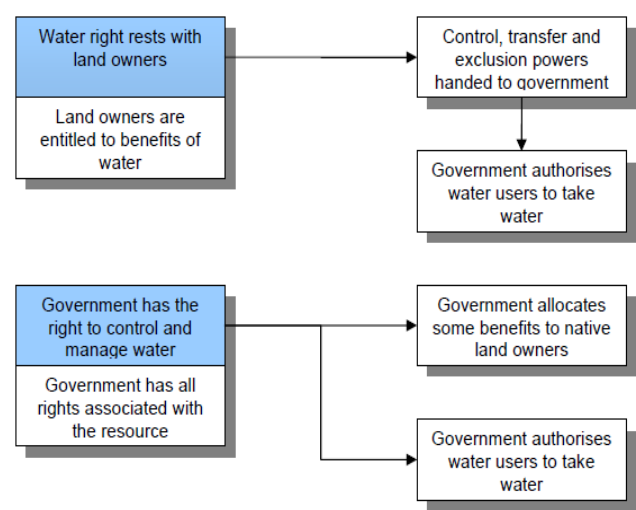

Figure 2.23: two legal opinions on right to use water (Water Policy Services Pty Ltd, 2006).

This draft policy, again, recognizes the absence of national legal framework and the need to protect water resources for environmental sustainability with continuing support needed for capacity building. The FG, though this policy, aims to clarify its legal status in being the custodian of all water resources, and recognizes that groundwater should be declared a mineral as defined in the Mining Act, although its susceptibility to pollution will necessitate special protection mechanism that do not apply to minerals (Water Policy Services, 2006). Further, the right to the flow, the use and management control of both surface water and groundwater is to be vested with the Government, which will exercise the national water management on behalf of the public of Fiji. This “2004 Draft Water Policy”, upon which future surface and groundwater management, allocation and exploitation acts were to be based, was never endorsed by Cabinet and needed further consultations. Recently, changes have been made to include both water resources management and sanitation.

2.6.2 Pilot Study

In 2006, the European Union (EU) funded a Fiji pilot study for the Programme for Water Governance (PFWG) with the intention to progress water resources management (WRM) at the national level in Fiji (Water Policy Services Pty Ltd, 2006). The study recognizes loopholes in the current water resources management set-up (Figure 2.24) and recommended the introduction of Integrated Water Resources Management (IWRM) and developments of specific responsibilities for WRM. It was recognized that pollution control, an aspect of WRM, is adequately covered by the Ministry of Environment (MoE), whilst other aspects, namely the allocation of water resources among all users, flood management, riverine controls and activities for water body protection as neglected (Water Policy Services Pty Ltd, 2006).

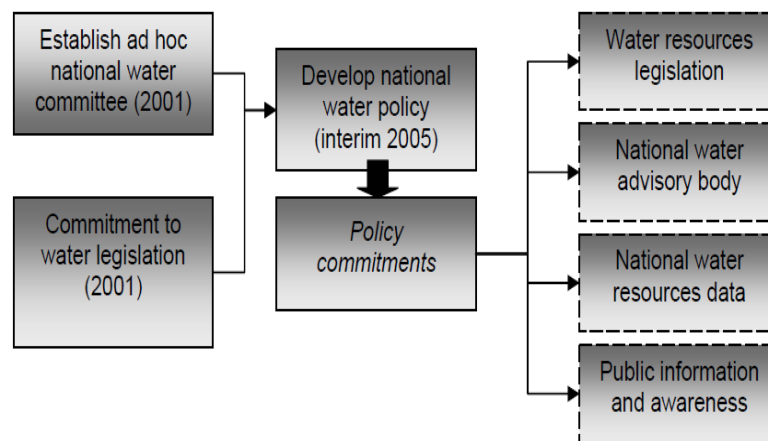

Figure 2.24: current water-related structure in Fiji Government.

Currently, some aspects of water resources management have been undertaken in a fragmented manner by either ad-hoc activities or default by various government departments, namely Department of Meteorological Services (DMS), Land and Water Resources Management (LWRM) Division of the Ministry of Agriculture, Hydrology Office of Public Works Department and MRD without adequate legislative backing. Hence, the need to develop a water resources department with regulatory power was recommended, as well as the implementation of IWRM. The function of this department was suggested to ensure the protection and sustainable development of water resources, without conflicting MoE's role of regulating wastewater discharge and environmental protection, with the equitable allocation and management of surface and groundwater likely to be addressed through:

- identification of volumes of water available and sustainable limits for various water users or types of water use;
- characterization of available water and flow conditions;
- statement or rules for ensuring flow for environmental and aesthetic values/benefits, and
- drawdown levels are determined and at which water abstraction should be limited;
- volumes of water various users may take and the rates at which water may be abstracted in known;
- various technical criteria such as minimum distance between bores for different users; and
- statement of priorities among water user in circumstances of low flow or water scarcity with rules and penalties for breaching these guidelines.

2.7 Stable Isotope Hydrology

2.7.1 Introduction

Isotope geochemistry is concerned with the measurement and interpretation of the variation of isotope composition that occur in elements of same atomic number but different atomic weight due to varying numbers of neutrons in the nucleus (Fetter, 2001). Stable isotopes are non-radioactive whilst radioactive isotopes undergo radioactive decays forming new elements and may even form stable isotope products, known as radiogenic isotopes. In hydrology, stable isotopes of hydrogen (H), oxygen (O), carbon (C), nitrogen (N) and sulphur (S) are commonly used to study processes that affect surface and groundwater whereas radioactive isotopes can be used to ascertain groundwater age. Although errors associated with chemical-extraction procedures continue to be a limiting factor in isotope analysis (Faure & Mensing, 2005), stable isotopes are gaining widespread recognition in the hydrology and geochemistry discipline.

2.7.2 Background of application in hydrology

Stable isotopes, in this study using hydrogen and oxygen isotope, is focused on the fractionation or separation of isotopes into light and heavy pairs caused by flux processes (e.g. condensation, evaporation, temperature changes) and controlled by difference in atomic mass and differences in their abundance in nature (Table 2.2).

| Isotope | Abundance (%) | Mass (amu) |
|-----------------|---------------|------------|
| ¹ H | 99.985 | 1.007825 |
| ² H | 0.015 | 2.014 |
| ¹⁶ O | 99.762 | 15.994915 |
| ¹⁷ O | 0.038 | 16.999131 |
| ¹⁸ O | 0.2 | 17.99916 |

Table 2.2: mass and abundances of H and O stable isotopes (Faure & Mensing, 2005).

Light isotopes, more abundant in nature (Table 2.2), have greater translational velocities, more reactive and have greater vibration frequency than heavy isotopes. Light isotopes also form chemical bonds with high degree of valency whilst heavy isotopes form stable molecular compounds and preferentially held in strong bonds (O'Brien, 2010). These control their behavior through a phase or across phase boundaries in processes, such as evaporation and diffusion. For example, light isotope can preferentially diffuse out of a system leaving a reservoir to be enriched in heavy isotopes. However, any substitution or replacement of light and heavy during these processes will not change the gross chemical properties of these elements or compounds but will have subtle changes chemical and physical differences in mass attendants as governed by the differences mentioned earlier (Sharp, 2007). In this study, H and O isotopes (the most abundant in the earth's crust) are analysed in a number of different water sources and detail of which will be covered in the later chapters. Table 2.2 shows that H has two stable isotopes whereas O has three meaning there are nine possible combinations of these isotopes that make stable water molecules with H₂¹⁶O dominating the abundance in the Hydrosphere (Table 2.3). Henceforth, H¹ or protium and H² or deuterium will be referred to as H and D, respectively.

| Isotope | Abundance (%) |
|--------------------------------|---------------|
| H ₂ ¹⁶ O | 99.73098 |
| H ₂ ¹⁸ O | 0.199978 |
| H ₂ ¹⁷ O | 0.037888 |
| HD ¹⁶ O | 0.031446 |
| HD ¹⁸ O | 0.0000006 |
| HD ¹⁷ O | 0.0000001 |
| D ₂ ¹⁶ O | 0.00000002 |
| D ₂ ¹⁷ O | 0.0000000001 |
| D ₂ ¹⁸ O | 0.0000000005 |

Table 2.3: average natural abundances of the nine (9) isotopologues of water vapor (Sharp, 2007).

The isotope ratios of H and O are measured by mass spectrometry and expressed relatively to standard mean ocean water (SMOW), conventionally plotted as meteoric water line (MWL) and derived by:

$$\delta D (\text{‰}) = 8\delta^{18}\text{O} + 10$$

This is due the near-linear relation between majority of waters D and ^{18}O and reinforcing that all waters are of meteoric origin and is used to reduce systematic errors in measurement made on different mass spectrometer. D and ^{18}O are therefore expressed in terms of a parameter called delta δ and through:

$$\delta^{18}\text{O} (\text{‰}) = [((^{18}\text{O}/^{16}\text{O}_{\text{sample}}) - (^{18}\text{O}/^{16}\text{O}_{\text{standard}})) / (^{18}\text{O}/^{16}\text{O}_{\text{standard}})] \times 1000$$

$$\delta\text{D} (\text{‰}) = [((\text{D}/\text{H}_{\text{sample}}) - (\text{D}/\text{H}_{\text{standard}})) / (\text{D}/\text{H}_{\text{standard}})] \times 1000$$

Isotope composition variability of H^{16}O and D^{18}O , as mentioned earlier, will show the enrichment (depletion) of heavy isotopes with respect to processes of precipitation, condensation and water-rock interaction. For instance, due to the Rayleigh fractionation, condensation and precipitation of air mass is common occur in windward and high altitude areas and cause heavy isotopes to preferentially diffuse out of the vapor phase and fall as rain (Sharp, 2007), and hence, water vapor moving into and precipitating as rain in the leeward side will be depleted in $\delta^{18}\text{O}$. Further, processes of water-rock interaction and mixing with magmatic waters can cause $\delta^{18}\text{O}$ to be release into solution and hence, groundwater or geothermal waters can enriched with the heavy isotopes (Figure 2.25)

Figure 2.25: isotopic composition of water in relation to MWL and oxygen shifts driven by either water-rock interaction or mixing with magmatic waters (O'Brien, 2010).

2.7.3 Previous Isotope Study in Fiji

A study was conducted around the islands of Viti Levu and Vanua Levu in the late 1970's to determine the origin of thermal waters and the characteristics of geothermal activity. Cox and Hulston (1980) documented the investigation and results of thermal and other waters in Fiji, which entailed the sampling

of 79 water sources, including thermal springs, hand-dug wells, rainwater and streams from the two main islands of Fiji (Figures 2.26 & 2.27).

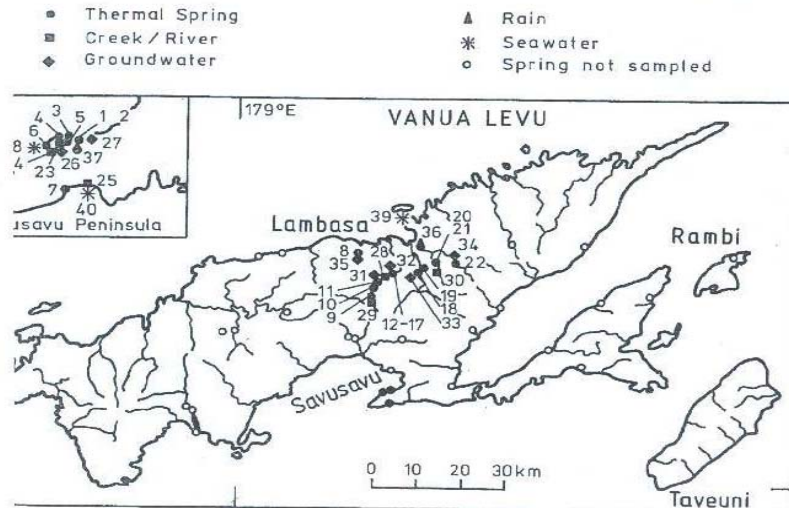

Figure 2.26: sample location around Vanua Levu (Cox & Hulston, 1980).

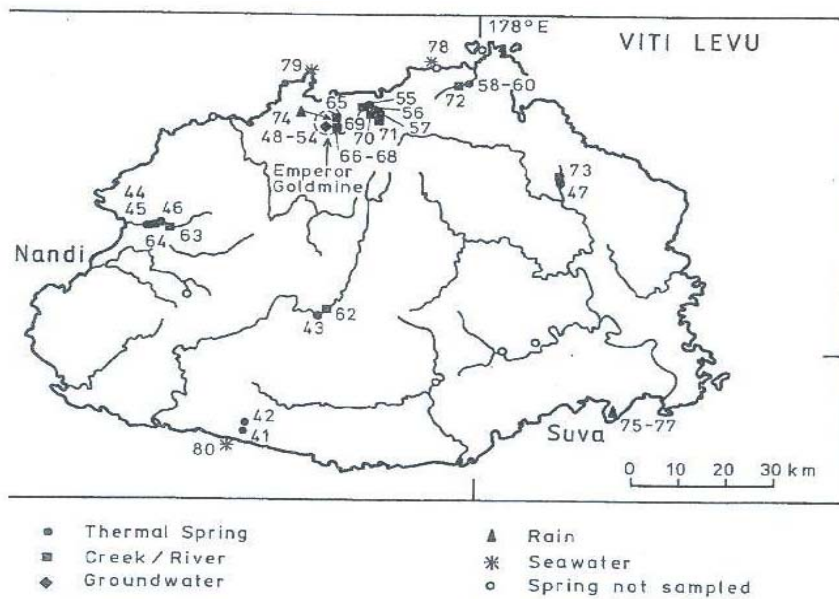

Figure 2.27: sample location around Viti Levu (Cox & Hulston, 1980).

These samples water analysed on $^{18}\text{O}/^{16}\text{O}$ and D/H ratios and chloride concentration. $^{18}\text{O}/\text{D}$ characteristics and composition were related to a best linear approximation of WML for the Fiji waters such that:

$$\delta\text{D} = 8\delta^{18}\text{O} + 13$$

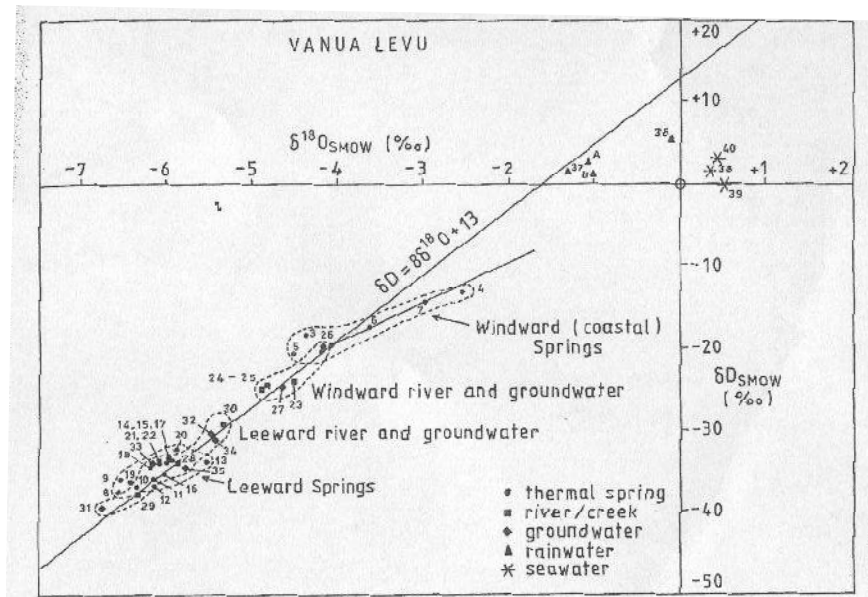

Figure 2.28: $\delta^{18}\text{O}/\delta\text{D}$ for Vanua Levu waters with signatures of seawater mixing in the windward thermal waters along a line with a slope of about 4.5 (Cox & Hulston, 1980).

Figure 2.29: $\delta^{18}\text{O}/\delta\text{D}$ for Viti Levu waters with strong evaporation of the leeward river water as shown by a line with a slope of about 5 (Cox & Hulston, 1980).

It was then concluded that Fiji thermal waters are of meteoric origin and their stable isotope composition is similar to the surface and shallow groundwater. Significant differences were attributed to mixing of other water (fresh groundwater, saline groundwater or sea water – particularly sites adjacent to the coast) (Figures 2.28 & 2.29). The overall isotopic data showed that most sample geothermal systems were

dominated by low temperature with no signatures (except Savusavu $\approx 150^\circ \text{C}$) of oxygen enrichment caused by high temperature rock-water interactions. The δD compositions of meteoric and thermal waters reflect the windward and leeward climatic conditions with an increasing depletion of deuterium in the leeward areas. Further, the difference in isotopic compositions in precipitation at different localities is attributed to temperature variations, different amounts of rainfall and seasonal changes in the wind direction (Cox & Hulston, 1980).

2.8 Conclusion & Synthesis

- The regional geology of the SW Viti Levu, Fiji is composed of Eocene to Recent arc and basinal assemblages and carbonate aprons formation (Wainimala Group), a period of plutonic intrusion (Colo Plutonic Group) and followed deposition and lithification of sediments (coupled with submarine mass wasting) (Tuva Sedimentary Group), periods of widespread displacements and deformation triggering further volcanism, with eustatic and base level fluctuations likely to control the aggradation of Quaternary-Recent Alluvium deposits onto incised bedrock.
- The study area, dominated by the highly deformed and juxtaposed Waimala and Tuva sedimentary groups, is dissected by the sinistral Nasovatava Fault, to which the deformation and displacements in the basement units is attributed and, with synchronous eustatic fluctuations, controlled the deposition of alluvial materials in the incised valleys.
- Groundwater use and exploitation around the Fiji islands has grown and resulting in the formation of the GRADU and has since been committed in the systematic development of groundwater for the benefit of wider communities and this is evident in the previous aquifer classifications of Fiji.
- Groundwater resources use and demand in the study area, as characterized by the rapid growth of PDW together with villages relying on springs and perennial stream catchments, is exceedingly high and will be serious concern during water deficit periods and may jeopardize the long-term sustainability of groundwater
- Despite several water-related legislations and numerous recent water-resources studies, the Fiji Government has **NO** legal framework to warrant the sustainable management and protection of groundwater resources.

- Isotope hydrology looks at the fractionation or separation into light and heavy pairs of stable isotope that occurs in fluxes, such as evaporation and condensation, and driven by the atomic mass and their abundance in nature. Previous studies in Fiji showed the dominance of meteoric waters in most of the sampled water bodies with minor differences attributed to mixing with saline and fresh groundwater.
- In summation, the tectonic and geological evolution of the southwest Viti Levu, together with eustatic fluctuation, have varying influences on the groundwater potential of the study area as substantiated by the previous rural development project in the Sigatoka Valley (SVRDP). One, however, may wonder if there are potential fractured units underlying the alluvium deposits (QRA) and if so, how would these fractured systems vary in terms of chemical and isotopic composition in relation to the origin and complexity of groundwater systems, as well as to previous studies. With the current growth on groundwater abstraction on the study area, it is critical that groundwater recharge and sustainability are established upon which the need for proper groundwater allocation and management legislative frameworks will be linked.

Chapter 3: Field investigation, methods and results

3.1 Engineering geology and geomorphological classification

3.1.1 Introduction

The field area is located in the middle Sigatoka valley, from Dubalevu to Bilalevu, and covers both sides of the Sigatoka River (SR). The major geological units observed, include the Tari Formation (TF) and the Qalimare Limestone (QL) of the Oligocene-Middle Miocene Wainimala Group (WG), juxtaposed Cici Sandstone (CS) and Takaro Conglomerate/Rudite (TCR) of the Late Miocene Tuva Sedimentary Group (TSG), and Quaternary to Recent Alluvium (QRA) deposits infilling the incised valleys (Figures 3.12 & 3.13) (Hathway, 1989 & Hathway and Colley, 1994). This section presents the lithological and engineering geology descriptions of the units based on the surface geomorphological mapping.

3.1.2 Methodology

Geological units were described/defined based on rock outcrop observations, although most geological contacts were obscured by thick vegetation cover and surface deposits. Surface outcrops were accessed by either vehicles or foot traverses through the hilly landscape to validate previously mapped units with geological nomenclature based on previous geological mapping around the Southwest Viti Levu region by Hathway (1989). Engineering geological classifications were also conducted based on Pettinga & Bell (1983) and NZ Geotechnical Society (2005) guidelines.

3.1.3 RESULTS

3.1.3.1 Geological units

3.1.3.1.1 WG

This group of rocks, dated Upper Oligocene to Middle Miocene (Hathway & Colley, 1994) and composed of the TF and the QL, is ubiquitous around the SSW-SSE of the study area and south of the ENE-WSW NF (Figure 3.13). The group had been interpreted as ungraded deposits of high density flows with minor stratified tops and carbonate debris apron deposited in deep water, respectively (Hathway, 1989 & Hathway, 1995).

3.1.3.1.1.1 TF

This Upper Oligocene to Middle Miocene formation, approximately 50 m in thickness and classified as polymict volcanoclastic rudites, limestone and lava (Hathway & Colley, 1994), appeared as moderately thin-thickly bedded and interbedded dark-brown argillite, grey-bluish grey sandstone, bluish grey to light grey dacite and dacitic tuff, light grey andesitic lava flows (abundant in quartz amygdales), and creamy claystone that is well indurated (Figures 3.1-3.3). The moderate-steeply inclined unit ($46-83^{\circ}\text{N}$ and $26-35^{\circ}\text{NW}$) appeared unweathered-moderately weathered, extremely-moderately strong, highly fractured (subvertical and sub-perpendicular to bedding orientation) with close spacing, narrow apertures, rough surfaces and with moderate to high persistence.

Figure 3.1: well indurated, extremely strong brown argillite composite of the TF (highly fractured with slickensided surface) observed at Bilalevu (Locality 1, Figure 3.12).

Figure 3.2: moderately weathered interbedded argillite and dacitic tuff of the TF observed at Vunarewa (Locality 34, Figure 3.12).

Figure 3.3: Extremely strong, fine to massive fabric, creamy claystone, well indurated, around Mavua (moderately incline ($20-25^{\circ}$) towards the NW) (observed at localities 17 & 18, Figure 3.12).

3.1.3.1.1.2 QL

This Lower to Middle Miocene Platform unit was observed as a white to creamy, massive to crudely bedded, limestone body dominated by cavernous weathering and moderate-highly fractured systems with sub-angular to sub-rounded volcaniclastics included (Figures 3.4-3.6). The limestone unit, 200-300 m in thickness, represents the upthrust component of the sinistral NF that protrudes the landscape as a north-facing ENE-WSW trending escarpment (NE of the study area) and extends for around 1 km towards the North (Figure 3.7). The unweathered-slightly weathered and extremely strong unit is moderately-highly fractured, as characterized by high persistence and wide-very wide apertures that is widely spaced. The QL steep and rugged terrain is covered thick vegetation cover, and flanked by scree and talus slopes comprising limestone cobbles and boulders and suggesting active hillslope processes.

Figure 3.4: cavernous weathering processes active in the Limestone unit.

Figure 3.6: Highly fractured QL (wide aperture and high persistence) and from which the Matanitavuni (Q3) spring discharges (locality 33, Figure 3.12).

Figure 3.5: sub-rounded andesite included in a massively bedded, white and extremely strong QL around locality 32 (Figure 3.12). Note book is 10cm×16.5cm.

Figure 3.7: north-facing QL escarpment protruding the NE corner of the study area and extending for around 1 km towards the NE.

3.1.3.1.2 TSG

This sedimentary group, interpreted as Late Miocene turbidite system in the Sigatoka Sedimentary Basin in age and ubiquitous around the WSW-ENE of the study area (Figure 3.13), is composed of the CS and TCR that were deposited during the erosion of the post-Colo and Wainimala arc (Sections 2.2.2 & 2.2.3) that supplied abundant epiclastic material to the Sigatoka Basin.

3.1.3.1.2.1 CS

This feldspathic litharenites unit, interpreted as a 600 m thick Late Miocene turbidite system (Hathway, 1989), was observed as a bluish grey to grey, fine-medium grained, well indurated, thickly bedded and interbedded sandstone, mudstone and siltstone (Figure 3.8). The unweathered-slightly weathered and extremely strong-moderately strong unit is ubiquitous around the N-NNW of the field area (Localities 16, 21-23, 39-42, Figures 3.12 & 3.13), and exhibited moderately-highly fractured systems (subvertical and sub-perpendicular to bedding orientations) (Figure 3.9), with low to moderate persistence and tight to narrow apertures (with quartz and calcite infill). The inclination of the unit varies from moderately inclined (24-26° SE) to steeply-inclined (40-47° SSE) and suggesting tectonic shortening overtime.

Figure 3.8: Moderately thick-thickly and steeply inclined CS around Rararua village (locality 21, Figure 3.12).

Figure 3.9: subvertical fractures with closely spaced and moderately wide aperture in the CS around locality 16 (Figure 3.12).

3.1.3.1.2.2 TCR

Outcropping at the hills N-NW Bilalevu and around Nabaka (localities 10-13, 15, 27, 35 and Figures 3.12 & 3.13), the Late Miocene high density mass flow conglomerate and rudites (and post CS formation) is thickly bedded and massive with dark grey matrix supported framework comprising fine silt and medium-coarse sandy matrix locking sub-angular to sub-rounded andesite, dacite, tonalite and limestone clasts. The unweathered-moderately weathered and very strong unit is highly fractured, closely spaced with narrow aperture (filled with quartz) and showing moderate-high persistence. The unit exhibits moderate inclination (20-28° SE).

Figure 3.10: outcropping TCR NW of Bilalevu (locality 13, Figure 3.12) showing sub-angular to sub-rounded andesitic and dacitic clasts locked in sandstone matrix.

Figure 3.11: sub-rounded andesitic boulders locked in sandstone matrix of the TRC around the Nabaka area (locality 27, Figure 3.12).

3.1.3.1.3 QRA

This alluvium unit, comprising materials transported and deposited by the Sigatoka River in response to Quaternary and Recent eustatic fluctuations, appeared to be around 25 m in thickness and composed of yellowish sandy silt with gravel beds comprising medium-coarse, sub-angular to sub-rounded, pebbles in Bilalevu. In Dubalevu, the distribution and extent of alluvial deposits is marked by the E-W trending abandoned meander bounded by the north and south facing steeply inclined sandstone hills. The alluvium materials are composed of flood overbank deposits on the east, whilst the western end is dominated by unconsolidated sandy gravels as validated by the drilling of wells 89/15, 90/15 and 90/16 during the Sigatoka Valley Rural Development Project (Davies, 1992).

3.1.3.2 Spring mapping

Five springs were investigated: three occur around the fractured QL in the Toga area, namely Koro-i-Ra (Q1), Nacule (Q2) and Matanitavuni (Q3), and two occur in the fractured TF at Vunarewa and Mavua, namely Mataukaba (V1) and Navala (M1), respectively (sites 31-33, 34, 36 in Figure 3.12) . Discharge in all but one spring responded rapidly to rainfall events, with Q2 recording constant flow throughout the year, suggesting that Q2 is recharged by both proximal and distal sources controlled by the persistence and connectivity of its fracture system. The other springs, although also occurring along fractured conduits, are controlled by fluctuations in the local water table responding rapidly to rainfall events and hence, a proximal recharge source. Q2 spring discharges approximately 2.2 L/s whilst the other springs recorded discharge rates of 0.1 – 10 L/s depending on the frequency/intensity of rainfall events.

3.1.3.3 Relevant geomorphic expressions

Several geomorphic markers helped constraint the surface processes that shaped the Sigatoka Valley. These include:

- two Quaternary to Recent terraces along the Sigatoka River course may also include buried river channels (potential groundwater sources) (Figure 3.13);
- two abandoned lakes (also called oxbow lakes) observed in (1) Nabaka and (2) Bilalevu representing areas of either groundwater recharge or groundwater discharge (Figure 3.13); and
- uplifted QL and steeply inclined CS proving deformations and displacements relative to the NF fault and its associated shear zones or fault splays, which may also be responsible for the initial development of fracture systems observed in the mapped geological units.

Figure 3.12: location map of surface outcrops locations within the study area. Summary of the mapped localities are presented in Appendix C.

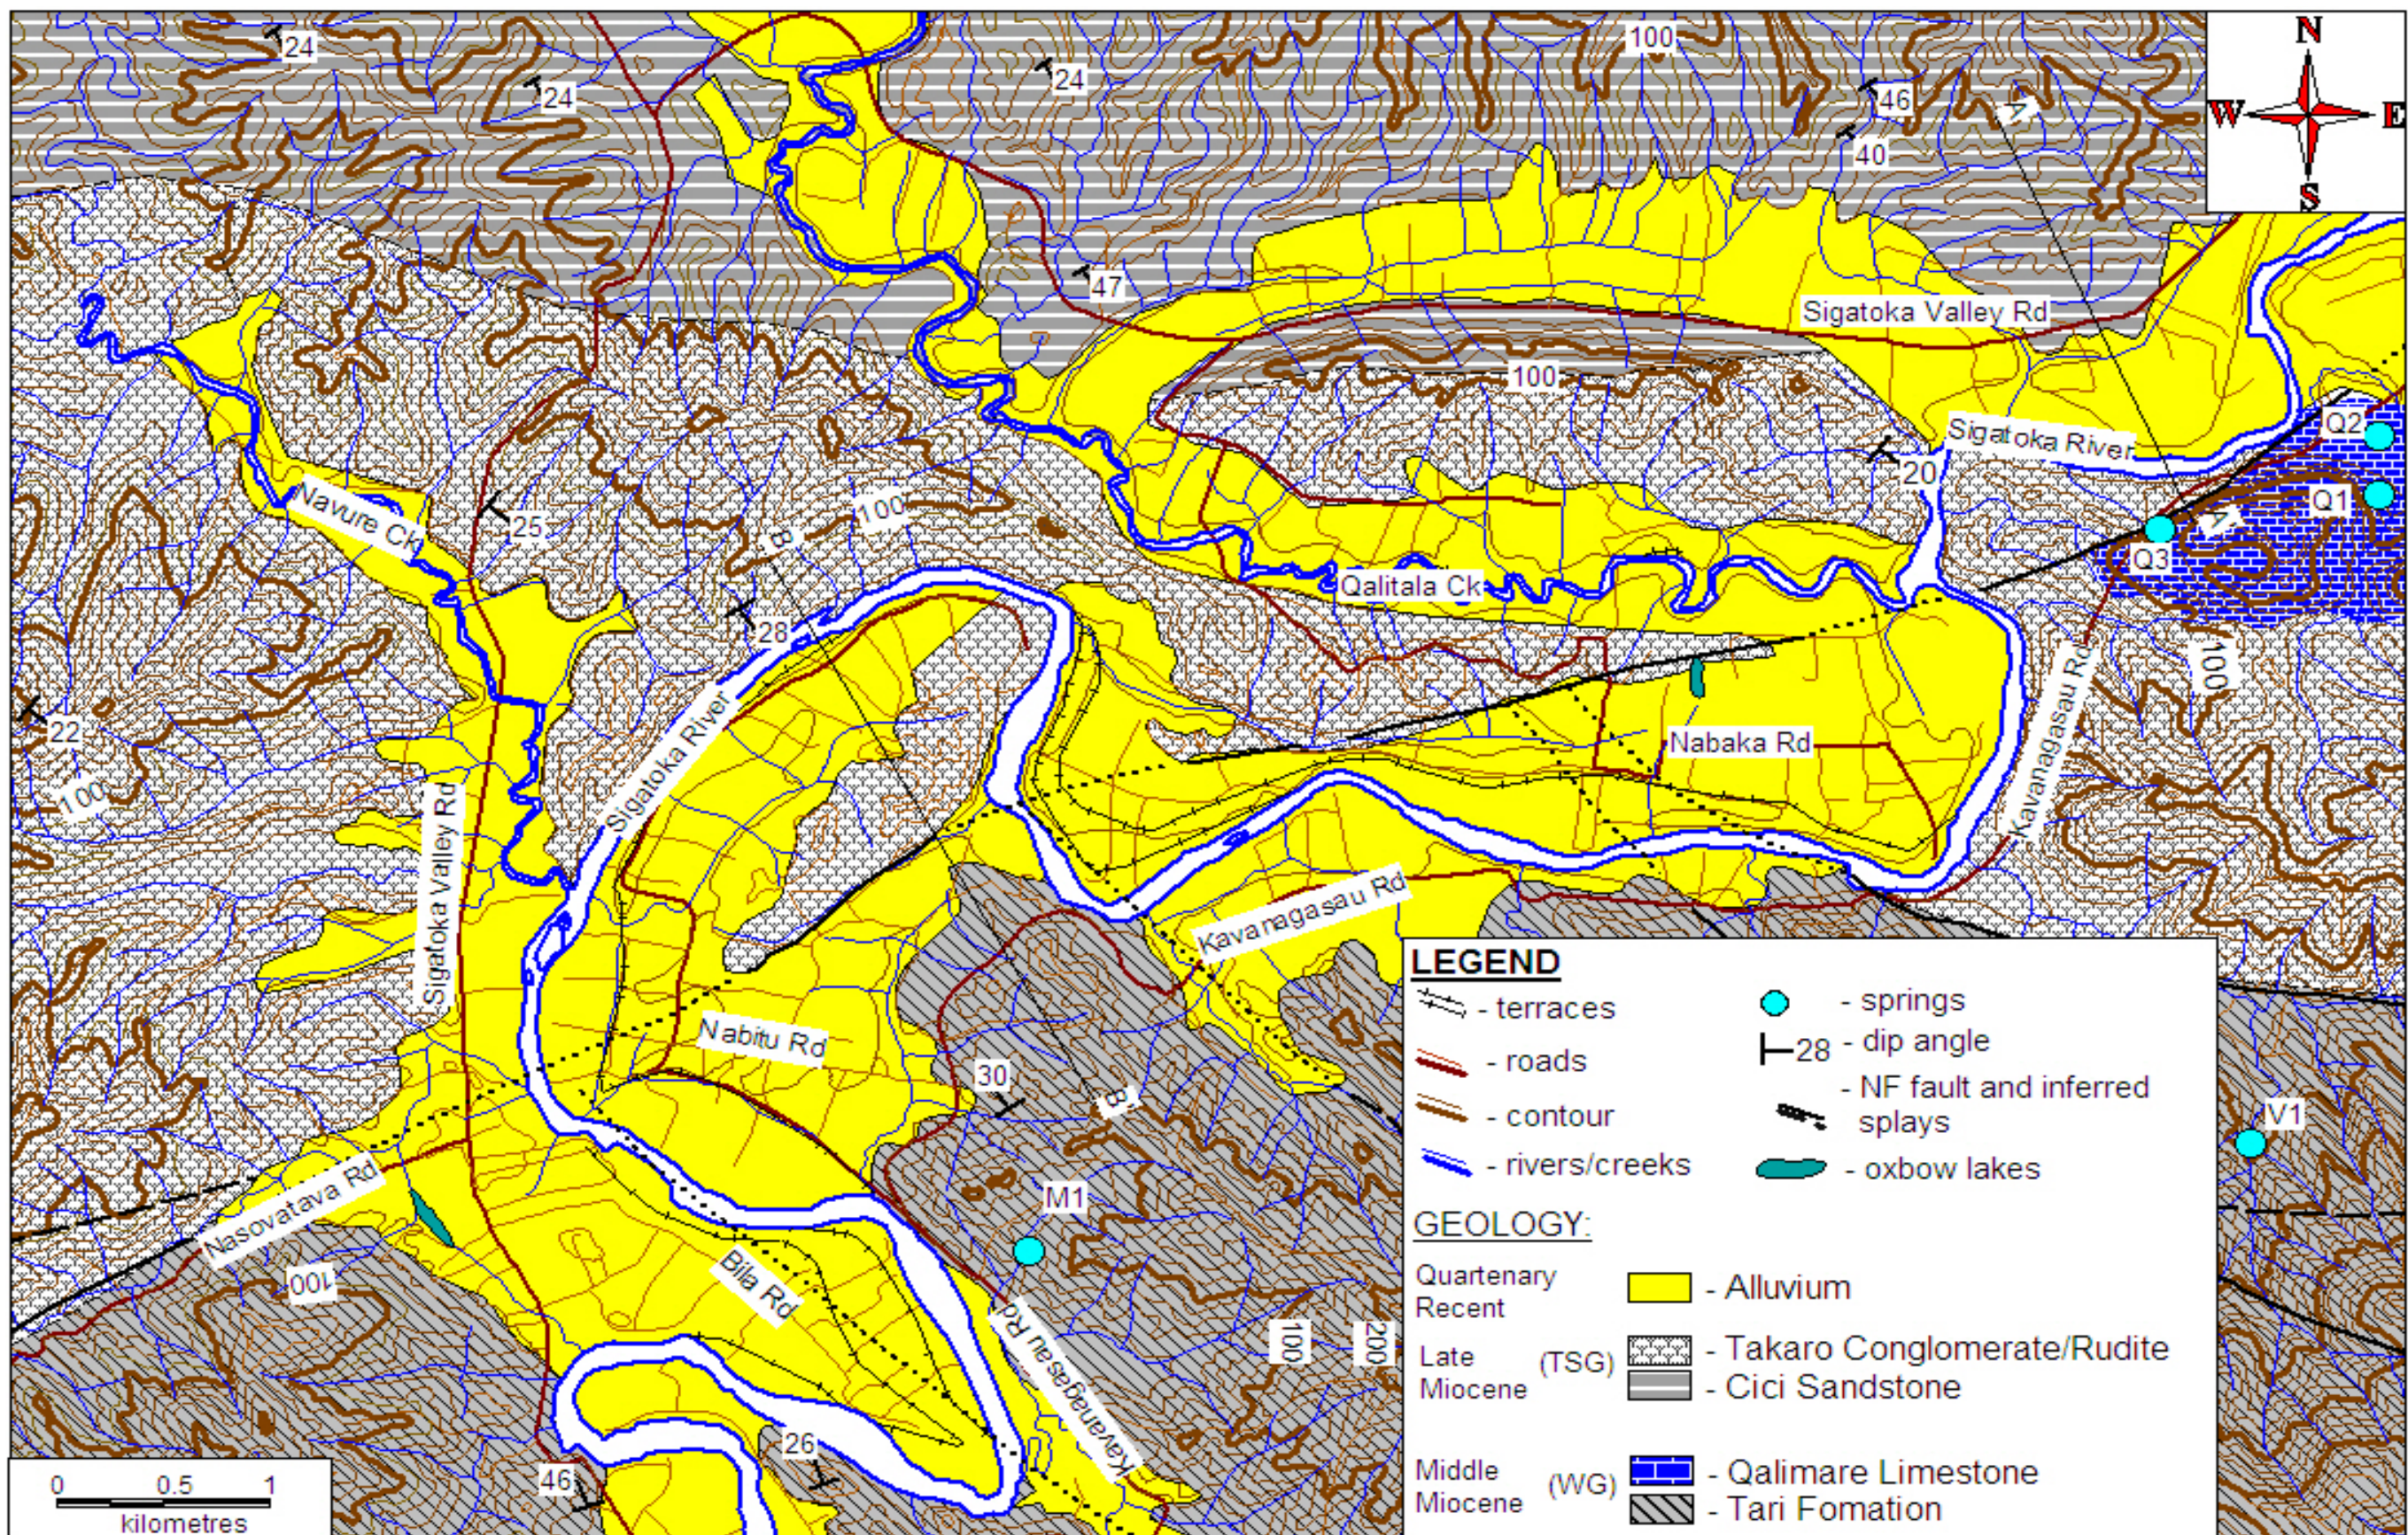

Figure 3.13: geological and geomorphological map of the study area showing Oligocene to Middle Miocene Tari Formation and Qalimare Limestone, Late Miocene Cici Sandstone and Takaro Conglomerate/Rudite and Quaternary to Recent alluvium, imprints of tectonic processes via the sinistral Nasovatava Fault (and its inferred splays), with a several geomorphic features, namely terraces, spring and oxbow lakes.

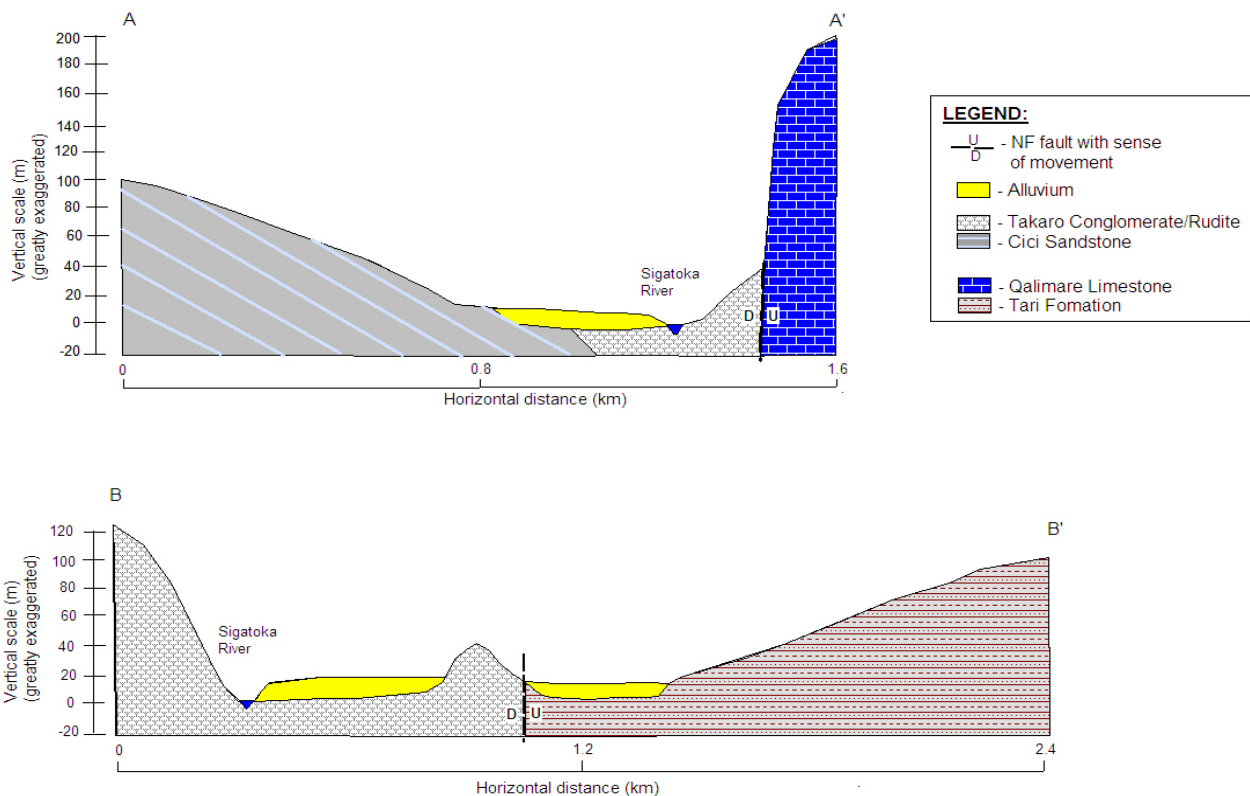

Figure 3.14: geological cross-sections at A-A' and B-B' showing the influence of the sinistral NF in dissecting the study area and may be responsible for the development moderate-high fracture systems observed in the mapped units.

3.1.4 SUMMARY

The above geological classifications and maps provide three contributions to the physical hydrogeology of the study area. First, the local sedimentary units represent either a low-negligible permeability basement or a fractured with moderate-high permeability basement governed by the fracture dimensions at depths. Second, the alluvial materials will be composed by either surficial silt-dominated confining units or unconsolidated sandy gravels representing buried river channels. Third, the presence of moderate-high fracture systems within the local sedimentary units, the uplifted Qalimare Limestone and the presence and close proximity of ENE-WSW trending sinistral fault (with its associated fault splays) suggest moderate-intense tectonic-induced shearing, which could create preferential groundwater storage and flow.

3.2 Geophysical survey

3.2.1 Introduction

The application of geophysics in hydrogeology is favoured due to its intrinsically non-invasive and non-destructive nature (Nobes, 1996) and its ability to produce high resolution subsurface models. In this research, two geophysical survey methods, namely electrical resistivity (ER) and electromagnetic (EM) methods, were used with the following objectives:

- to show water table depth, determine maximum thickness and spatial extent of Quaternary-Recent alluvium (QRA) materials;
- to estimate depth to bedrock;
- to identify subsurface anomalous structural features, such as folds, fracture density and faults, which are propitious for groundwater flow and storage; and
- to select potential drill sites

The following sections outline the methodologies and results obtained from these surveys. Details of site conditions, survey designs and background information of electromagnetic and resistivity methods, as well as field raw data are presented in Appendix D.

3.2.2 Methodology

Site reconnaissance, with the aid of API and surface geological mapping, permitted the selection of the subjective survey areas in Dubalevu, Tubakeli and Bila Rd (Figure 3.15). Borehole logs and water levels measurements data of existing boreholes were measured, using Solinst TLC depth probe, and were recorded beforehand (Tables 3.2 & 3.3). The geophysical surveys were conducted several days after Tropical Cyclone Mick (TCM), which caused widespread flash flooding around the area. Two geophysical survey systems were used, namely EM34-3 Geonics and Supersting Avi Ip, with one (1) line of each method used in Dubalevu, two (2) EM and three (3) ER lines were laid in Tubakeli while both methods were run twice in Bila Rd (Figure 3.16 & 3.17). The EM equipment, comprising transmitter and receiver coils, was used in the horizontal coplanar coil orientation (also called vertical dipole (VD)) and in the vertical coplanar coil

orientation (also called horizontal dipole (HD)) (Figures 3.18 and 3.19). Two conductivity readings were generated and recorded at each site. The VD measures subsurface voluminous conductivity to a maximum depth of 1.5 times the coil separation whilst the HD gives conductivity to a maximum depth of 0.75 times the coil separation (Table 3.1). Reading stations were marked at 5 m intervals. Survey lines were laid such that either two or three different coil separations, namely 10 m, 20 m and 40 m, were used and during which VD and HD measurements were recorded manually on field data sheets (Figure 3.18) and subsequently stored in Microsoft Office Excel format. Due to the presence of several cultural features around the study areas, the raw data were deemed noisy (Dr David Nobes, University of Canterbury, pers.comm, 2010) (Appendix 3.2). The data quality was improved through the process of convolution and using the 5-point running mean tapering formula (Dr David Nobes, University of Canterbury, pers.comm, 2010) given by:

$$\text{Conductivity at reading } X_{(i)} = (X_{(i-2)} + 2 * X_{(i-1)} + 3 * X_{(i)} + 2 * X_{(i+1)} + X_{(i+2)}) / 9$$

The ER equipment (Figure 3.20), powered by two 12V batteries (Figure 3.21), was designed and set-up such that the ER lines ran either perpendicular or parallel to the EM lines. In-built programs of Schlumberger and dipole-dipole strong gradient (DDSG) arrays were selected and initialised prior to the survey. Procedures, such as adequate grounding of steels pegs and contact resistance test, were followed prior to the start of survey. The Supersting Avi Ip equipment has an estimated resolution of 0.25 times the length of the survey line and all of the survey lines were around 280 m in length. The measured resistivity values were recorded in the Supersting Avi Ip equipment and downloaded into a desktop PC using the dongle provided. Survey raw data were then loaded into EarthImager 3.2 where the raw data were converted through in-built algorithms, before using an inversion process to produce subsurface models/profiles.

3.2.3 Results

The following sections will show location maps of survey areas, measured groundwater level, DDSG electrical resistivity profiles, as well as HD and VD electromagnetic responses.

Figure 3.15: location map of geophysical surveys areas that were selected to explore the presence of fractured or shear zones related to the inferred structural features at Tubakeli and Bila Rd and the continuity of the gravel aquifer, as well as any fractured bedrock system, in Dubalevu.

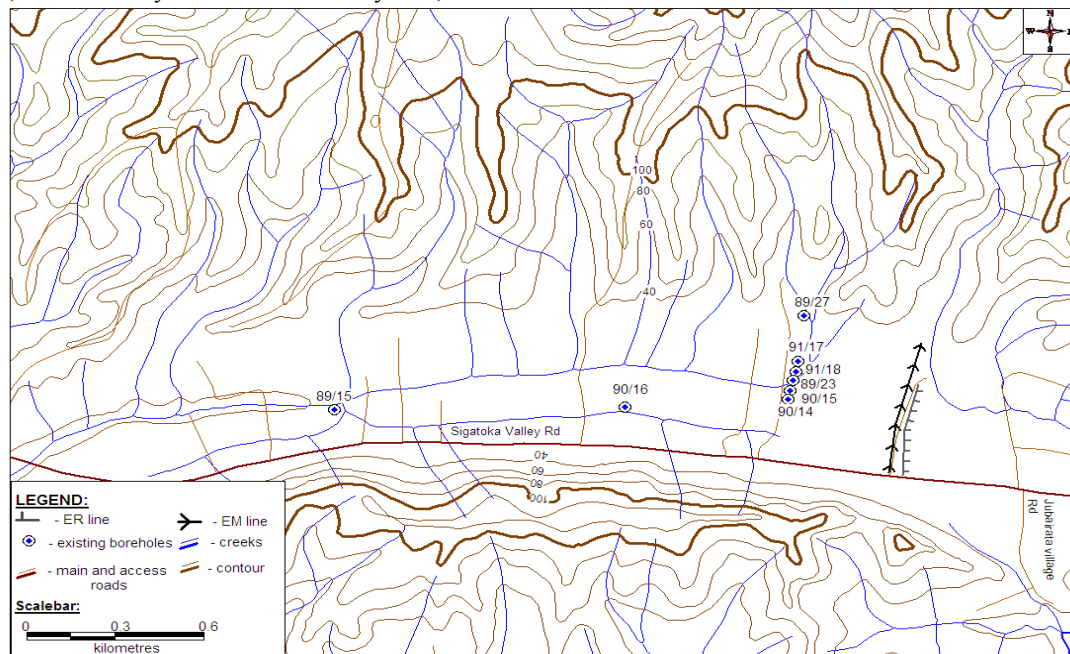

Figure 3.16: location map of geophysical lines on the E-W trending abandoned meander at Dubalevu with the adjacent existing boreholes which were measured for a priori (Table 3.2). Note that boreholes 90/15, 90/16 and 89/15 are irrigation sources drilled into unconsolidated sandy gravel during the SVRDP (see section 2.5.3). This survey permitted the assessment of extent of this gravel aquifer to the western end of the abandoned meander.

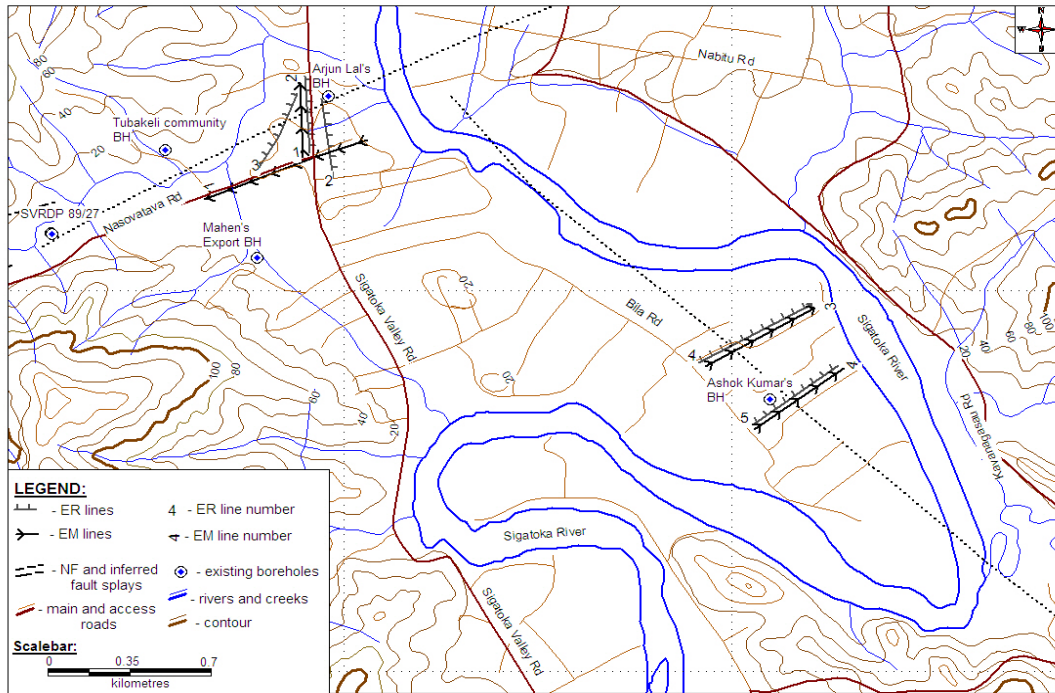

Figure 3.17: location map of geophysical lines at Tubakeli and Bila Rd with adjacent existing boreholes that were measured for a priori (Table 3.3). Note that the surveys lines were oriented either along or perpendicular to the sinistral fault and its inferred splays to investigate of possibility of high fracture density of shear zones related to these structural features.

| Intercoil Spacing (m) | HD | VD |
|-----------------------|-----|-----|
| 10 | 7.5 | 1.5 |

Figure 3.18: EM34-3 receiver coil on a horizontal coplanar arrangement (also called vertical dipole (VD)) with the readings manually recoded on a data sheet.

Figure 3.19: EM34-4 transmitter coil in a vertical coplanar arrangement (also called horizontal dipole (HD)).

Figure 3.20: Electrical resistivity equipment, Supersting Avi Ip.

Figure 3.21: two 12V batteries used as power sources for ER survey.

Figure 3.22: DDSG resistivity profile of Dubalevu a with very high resistivity zone at depth (possibly indicating deformed bedrock (CS) with a bedrock high between 30-90 m ER positions before an increasing depth to around 26-33 m depths after 90-100 m ER positions. The zone of very low resistivity may represent QRA flood overbank deposits that is saturated from TCM rainfall.

Figure 3.23: Dubalevu HD showing a uniform increase in EM responses beyond 100 m reading positions suggesting increasing thickness of QRA, increasing depth to bedrock and possibly increasing fracture densities (possible water sources).

Figure 3.24: Dubalevu VD show a noisy dataset with uniform peak responses between 240-280 m reading positions and suggesting possible fracture zone at 15-60m depth.

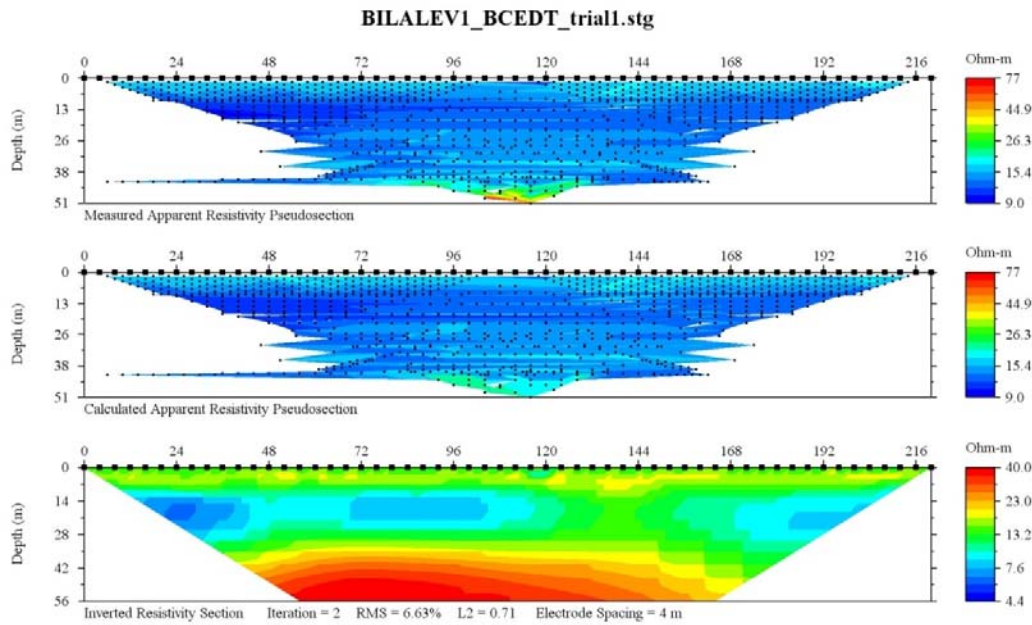

Figure 3.25: DDSG profile of line 1 at Tubakeli, Bilalevu showing an erroneous ER profile, as characterized by a field dataset dominated by very low resistivity values and subsequently inverted to a stratified profile; this was attributed to improperly connected electric cables.

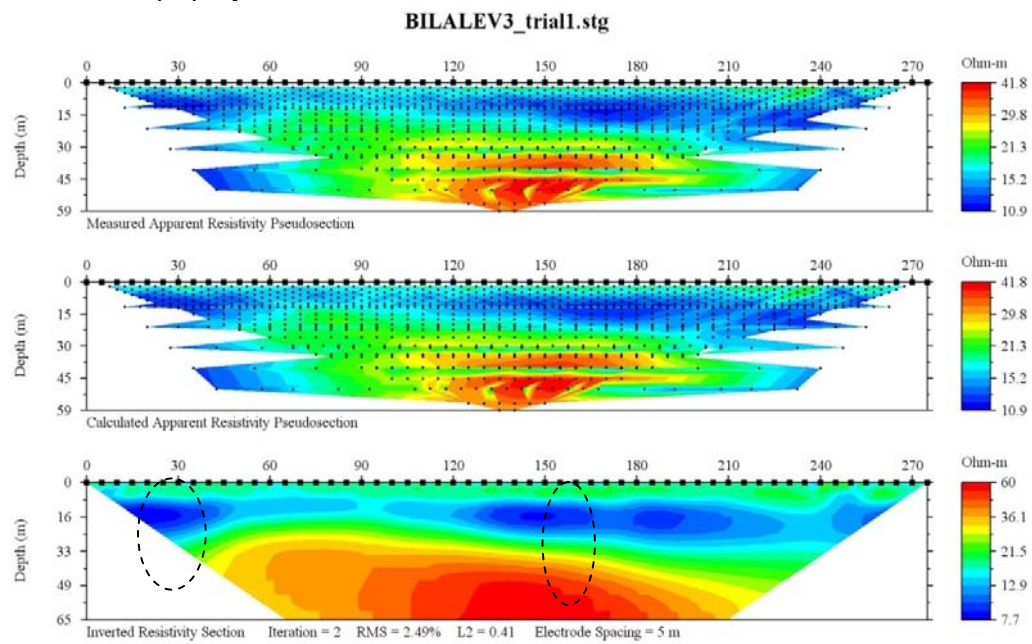

Figure 3.26: DDSG profile of line 2 at Tubakeli, Bilalevu showing high resolution ER profile of TCR bedrock with potential drill sites (denoted by dashed ovals) on Mr Hari Chand's farm.

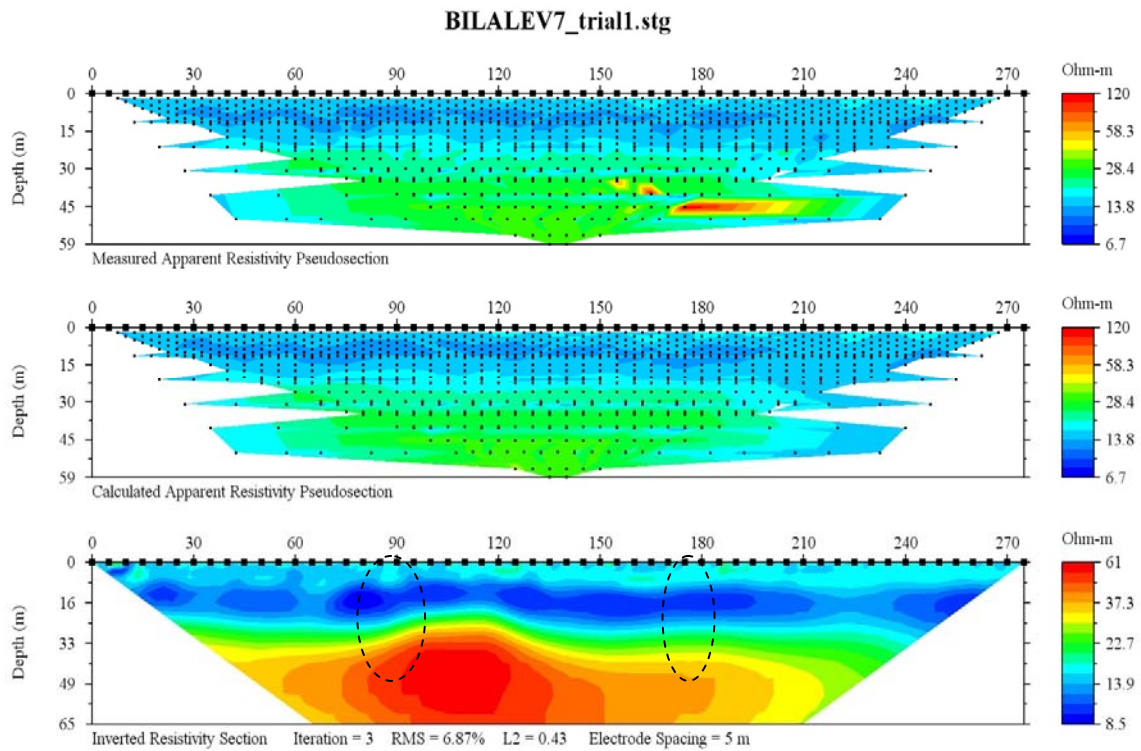

Figure 3.27: DDSG profile at line 3 at at Mr Umesh and Mr Sanjay’s farm in Tubakeli showing a zone high resisity from 40-65 m depths (possibly bedrock) and surrounded intermediate resistive zone, suggesting weathered or fractured composited. Areas low resistivity may indicated saturated overbank flood deposits. The dashed oval represent areas of possible fractured systems as shown by 20-m VD peaks and hence, potential drill sites.

Figure 3.28: EM line 1 HD reponse at Tubakeli showing high anomalously high readings from 40-m separation suggesting a fractured or sheared zone at around 30 m depth.

Figure 3.29: EM line 1 VD at Tubakeli consistently showing anomalously high 40-m separation response and sugesting fractured basement.

Figure 3.30: EM line 2 HD at Tubakeli showing relatively uniform and higher 20-m separation response suggest slight altered porosity at around 15 m depth. The lower 10-m response may suggest homogeneous material to 7.5 m depth (possibly overbank flood deposits).

Figure 3.31: EM line 2 VD at Tubakeli showing fluctuating responses of 20-m separation and suggests presense of possible fractured system around 35 m depth between 60-100 m and 150-180 m EM positions. Hence, two potential drill sites have been selected as denoted by dashed oval.

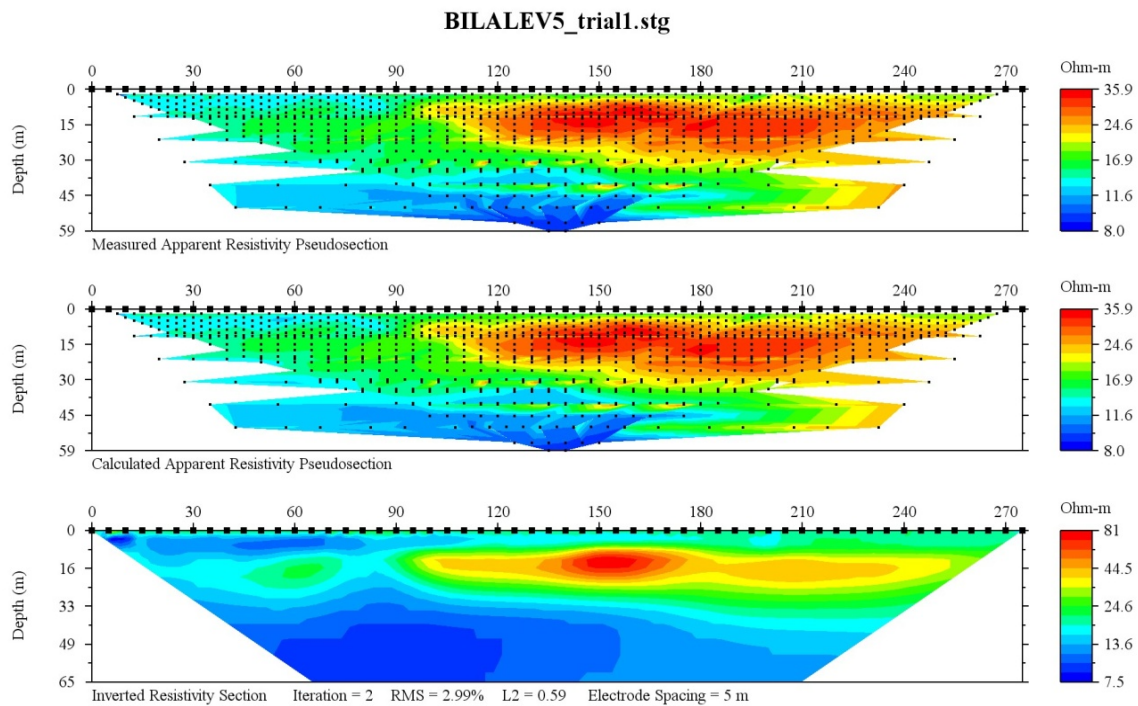

Figure 3.32: ER profile at Ashok Kumar's farm, Bila Rd, Bilalevu showing low resistive bedrock suggesting highly sheared or fractured basement unit between 60-90 m ER position with a band of high resistivity, which may indicate a buried gravel bar.

Figure 3.33: EM line 3 HD at Ashok Kumar Billa Rd, Bilalevu showing anomalously high 40-m and 20-m separation responses in the first 60 m of EM positions suggesting fractured bedrock between 15-35 m whilst the decreasing response beyond 190 m represents the influence of buried highly resistive gavel band inferred by the ER profile.

Figure 3.34: EM line 3 VD at Ashok, Kumar Billa Rd, Bilalevu showing a noisy dataset with relatively high 40-m and 20-m separation responses in the first 100 m of EM positions suggesting fractured bedrock between 35-60 m whilst the decreasing response beyond 120 m represents the influence of buried highly resistive gavel band shown on the ER profile.

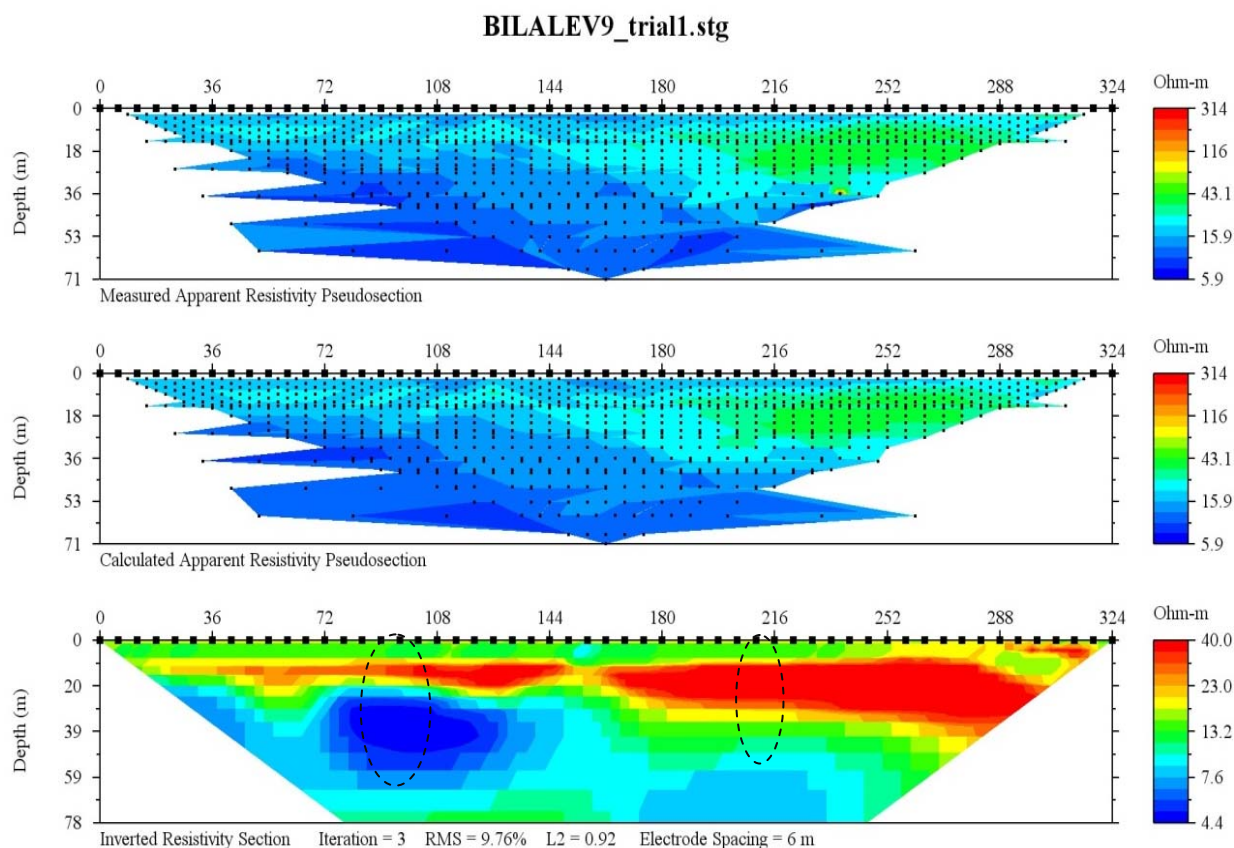

Figure 3.35: DDGS line 5 profile at Sugar Ram's farm at Bila Rd showing a possible sheared bedrock at 28-48 m depths between 72-110 m ER positions together with an inferred gravel bar characterised by very resistive zone around 10-20 m depths. Hence, two potential drill sites have been selected as denoted by dashed oval.

Figure 3.36: EM line 4 HD at Sugar Ram's farm, Bila Rd, Bilalevu showing a relatively high response of 20-m separation suggesting altered porosity at 15m depths whilst the decreasing responses of all coil separations towards the end suggests the influence of the buried gravels bar in attenuating the emitted signals.

Figure 3.37: EM line 4 VD at Sugar Ram's farm, Bila Rd showing a noisy dataset with higher response of 20-m and 40-m separations supporting the the presence the sheared bedrock between 35-60 m depth, while the decreasing trend towards the end of the line suggests the influence of the inferred gravel bar attenuating all the emitted electric current and hence, inducing low EM response for all coil separation. Two potential drill sites, denoted by dashed ovals, have been selected.

The above geophysical data and interpretations make three the contributions to the physical hydrogeology of the study area. First, the surficial low resistivity bands at Dubalevu and Tubakeli suggest 5-10 m silt-dominated alluvium, whilst the anomalously high resistivity band observed at Bila Rd, suggested a sandy gravel unit (potentially a buried river channel) between 10-20 m (a potential groundwater source). Second, the undulating and slightly weathered sedimentary basements are very well represented in the Dubalevu and Tubakeli ER profiles between 15-60m depth, whilst the anomalously low resistivity response in the Bila Rd basement suggest highly sheared or fractured unit at 30-60 m depth. Third, the fluctuating EM responses in all survey area, particularly with 20-m and 40-m separations, suggest that presence of fractured basements, and potential groundwater sources, in places between 30-60 m depth. Fourth, the above estimated fractured zones, particularly in Tubakeli and Bila Rd, are likely to be related to the sinistral ENE-WSW fault and its associated shear zone, which is believed to be propagating along Bila Rd and hence, suggesting the influence of structural controls on hydrogeological conditions.

3.3 Permeability test

3.3.1 Introduction

The “Falling head” method, suitable for testing the hydraulic conductivity (K) of fine grained soils, namely silts and clays (Mr David Bell, Senior Lecturer, University of Canterbury, pers.comm., 2009), was conducted on soil samples from Dubalevu and Bilalevu (previously classified in Chapter 1) to determine:

- K of the capping soil; and
- the rate of vertical recharge via infiltration from meteoric and irrigation water

3.3.2 Methodology

Soil samples were collected insitu after mud pits of a several drill holes, namely 10/07, 10/12 and 10/15, were dug (Figure 3.38). The permeater cell was carefully driven onto the 2 m × 1 m × 1 m mud pit wall to procure the samples. Samples were trimmed on both sides of the cells before adequate compaction, using compaction hammer, was applied to prevent having air spaces and leakages on the sides. Wire gauze was placed on both sides of the permeater cell before it was placed in the cage and was clamped evenly to the top by a clamping plate. The top inlet of the permeater cell was connected to a stand pipe, which in turn was connected to a storage tank. The permeater was immersed in to bucket of water to assist de-airing: a discharge outlet was made on the side of the bucket slightly above the top of permeater cell to which the bucket was filled. The sample was saturated (through the standpipe water from the storage tank) for 24 hours. The top inlet of permeater was closed using a pinch clip before the standpipe was filled to a suitable level, disconnected from the storage tank and placed at a known height. The initial level of the standpipe (h_0) was recorded before the timer started upon the release of the pinch clip and the instantaneous change in head (h) was measured at different times.

The formula used to determine K of the tested sample is

$$K = (a/A) \times (L/t) \times \ln\{h_0/h\} \text{ or } K = 2.3 (a/A) \times (L/t) \times \log_{10}\{h_0/h\}$$

where K = hydraulic conductivity (m/s)

a = standpipe area (m²)

A = sample cross sectional area (m^2)

L = sample thickness or height (m)

h_0 = initial head above top of sample (m)

h = measured head during or at the end of test (m)

t = elapsed time from h_0 to h (sec)

3.3.3 Results

| Site | Hydraulic conductivity (K) (m/s^{-1}) |
|----------|--|
| Dubalevu | 7.8×10^{-8} |
| Tubakeli | 2.2×10^{-7} |
| Bila Rd | 4.3×10^{-8} |

Table 3.4: measured K using the WF26010 Falling Head permeability cell showing low K values and suggesting relatively slow infiltration from meteoric and imported waters through the vadoze zone (test results area shown in Appendix E).

The above result makes a major contribution to the physical hydrogeology of the Middle Sigatoka Valley. The low permeability values suggest that infiltration of meteoric and irrigation water through the silt-dominated soil and vadoze zone will be relatively slow.

3.4 Groundwater drilling, development and evaluation

3.4.1 Introduction

This section denotes the methods and results of groundwater drilling, development (through construction and flushing) and hydrogeologic pumping test assessments.

3.4.2 Methodology

3.4.2.1 Groundwater drilling

The objectives of the groundwater drilling were to:

- validate the inferences of geophysical surveys;
- assess lithological samples in relation to surface geological units; and
- determine the depth and thickness of aquifers (if any).

Borehole depths were targeted to either completely or partially penetrate the inferred alluvial and fractured sedimentary units. The drilling of nine boreholes within the Dubalevu and Bilalevu areas was conducted through the mud-rotary circulation method (Figure 3.38). Boreholes were targeted for 203 cm outside diameter (OD) to permit the use of maximum possible pump size and leaving adequate allowance for the depth probes during the evaluation stages. However, inadequate supply of 203 cm plain and slotted piping resulted in the drilling only one 203 cm OD borehole, namely 10/07, with the rest of the boreholes wells drilled to 152 cm OD. Drilled cuttings were collected at one meter intervals and washed for lithological description. Geological contrasts, including abrupt changes in lithological properties, were noted relative to possible groundwater occurrence and movement. Several disadvantages were encountered with the drilling methods including:

- samples contamination by mud such that the presence of fine materials were difficult to recognize;
- distorted representation of drill cutting samples due to the high level of mixing from sediments and samples from layers above the drilled depth; and
- tendency of drilling mud to infiltrate the investigate aquifer systems causing difficulty to remove deeply infiltrated mud during well development (Davies, 1989).

3.4.2.2 Well construction and development

Wells were constructed/developed to ensure the longevity and stability of the boreholes. Locally purchased plain and 3 mm slotted PVC pipes were used before adequate gravel packing was applied to act as groundwater filters. Cement grouting was applied on the top 2 m of every borehole to avoid the infiltration of storm water into the boreholes before borehole caps were installed for well protection. All boreholes were adequately purged (Figure 3.42) through compressed air, together with the use of surging and jetting tools, to clean well screens, permit the settling of gravels outside the screens and to ensure that low groundwater turbidity is maintained prior to the evaluation stage. During the flushing stages, well potential estimates were determined in order to select the most appropriate pump-size for subsequent groundwater evaluation (Table.3.5).

3.4.2.3 Aquifer evaluation via pumping tests

This was conducted on six of the nine recently installed wells with the following objectives:

- to calculate the aquifer properties, namely transmissivity (T), storativity (S) and hydraulic conductivity (K); and
- to establish the potential of the aquifer and permit the collection of chemical and isotope samples.

A mono-pump, powered by Lister-Petter engine, with a maximum capacity of 11 L/s, was used to evaluate wells 10/07 and 10/12 (Figures 3.43 & 3.44). Boreholes 10/08 and 10/13 were evaluated using a 1 L/s pump due to their low well potential estimate, whilst a 3 L/s Grundfos submersible pump was used to 10/14 and 10/15 (Figure 3.45). The pumps were lowered down to the middle of the inferred aquifer to capture maximum aquifer flow. Step drawdown tests were conducted on boreholes 10/08 and 10/13 to select the ideal discharge rate to be used during the long-term test, while the unavailability of a suitable sized pump for 10/14 and 10/15, as well as the difficulties of the inserting and retrieving the depth-probes (due to the vibration of mono-pump column pipes) into 10/07 and 10/11 prevented the step-drawdown analysis. Hence, these boreholes were analysed for long-term constant-rate tests (as per well estimate in Table 3.5), whilst the nearest available boreholes (10/10 and 10/12, respectively) were monitored full-time for drawdown and recovery responses. Solinst depth probes, stop watches and a 14 L bucket and a 200 L drum were used to

measure pre-pumping static water levels together with depth to water table and discharge during the pumping tests (Figures 3.46 & 3.47). Aquifer parameters (T, K and S) were estimated by either the Theiss curve-matching method or the Cooper-Jacob straight-line approximation or both, depending on the availability of an observation well.

3.4.2.4 Groundwater monitoring

Groundwater levels were monitored during two periods, namely 31/08/10 and 02/10/10 (Tables 3.7 & 3.8). In each period water levels were measured for a number of wells in Dubalevu and Bilalevu to generate the potentiometric surfaces in these two areas. Water level measurements, taken at the top of PVC pipe casing, were taken using a Solinist TLC model dipper and measurements were taken before PDW in Bilalevu were pumped for drinking purposes with all irrigation sources in Dubalevu not currently used due to pump problems. Locations and elevation data of the wells were captured using Garmin76 GPS device for GIS use. Water levels measured from the two monitoring periods were imported into Golden Software Surfer 9.0 to create contour surfaces, which, in turn, were exported in a compatible format to be used for GIS purpose in MapInfo10.0.

3.3.3 Results

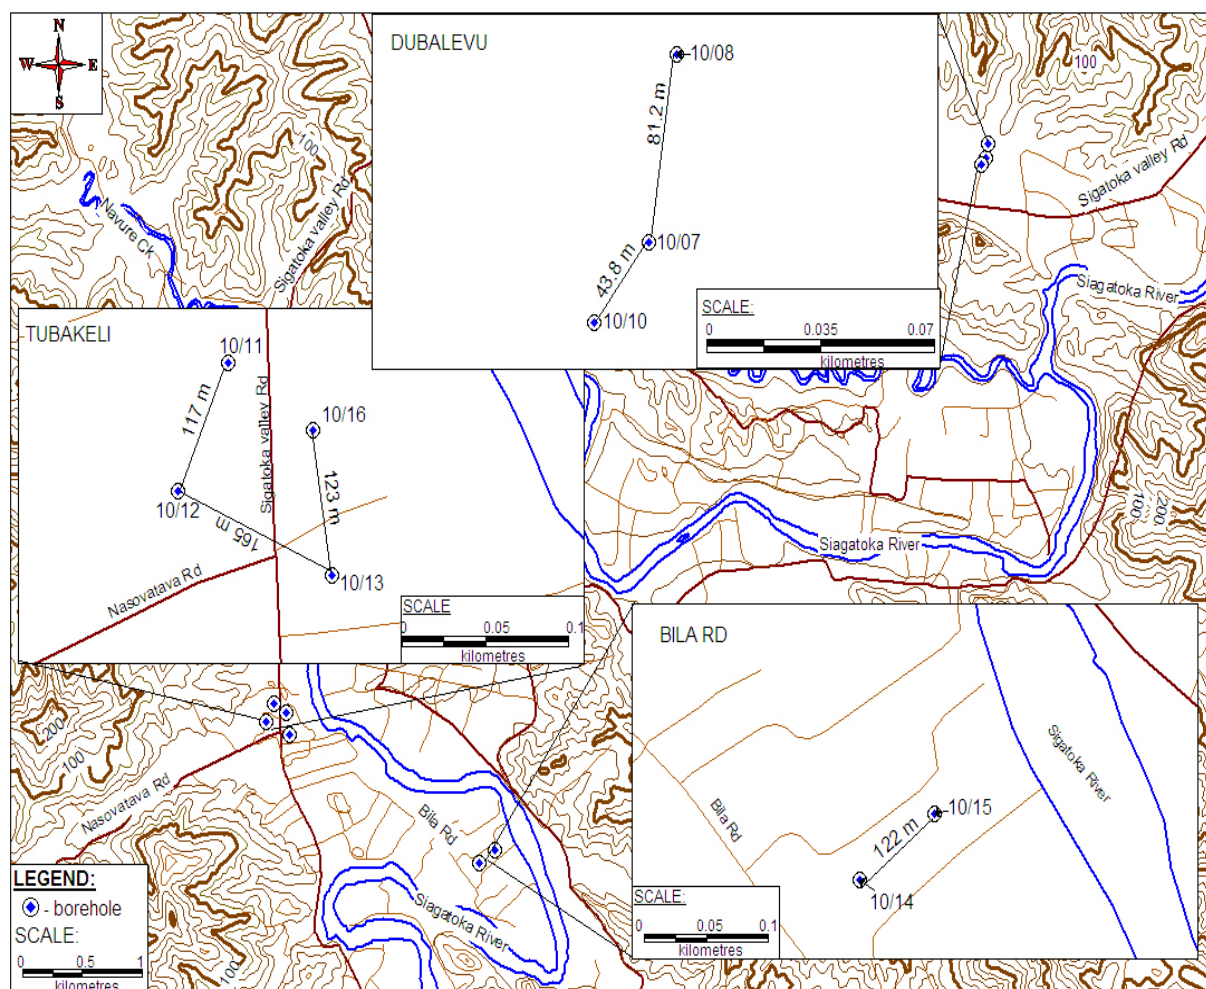

Figure 3.38: Location of boreholes with unique numbers (depth): three (3) in Dubalevu (10/07 (34 m), 10/08 (28 m) and 10/10 (36 m)), Tubakeli (10/11 (41 m), 10/12 (43 m), 10/13 (31 m) and 10/16) and Bila Rd (10/14 (60 m) and 10/15 (35 m)).

| Well Number | Location | Depth (m) | Outside diameter (mm) | Aquifer thickness (m) | Estimated Flow (L/s) |
|-------------|----------|-----------|-----------------------|-----------------------|----------------------|
| 10/07 | Dubalevu | 34 | 203 | 10 | 6-7 |
| 10/08 | Dubalevu | 28 | 152 | 5 | 0.3-0.5 |
| 10/10 | Dubalevu | 36 | 152 | 11 | - |
| 10/11 | Tubakeli | 41 | 152 | 3 | 3-4 |
| 10/12 | Tubakeli | 43 | 152 | 5 | 4-5 |
| 10/13 | Tubakeli | 30 | 152 | 3 | 0.4-0.6 |
| 10/14 | Bila Rd | 60 | 152 | 5 | 3-4 |
| 10/15 | Bila Rd | 35 | 152 | 6 | 1.8-2 |
| 10/16 | Tubakeli | 31 | 152 | 1 | 0.05-0.1 |

Table 3.5: summary of drilled wells around the Dubalevu, Tubakeli and Bila Rd areas with the well potential estimates attained from well flushing. Note that the estimated aquifer thicknesses are estimated from zones of concentrated geological contrasts as per well lithological log (Individual well logs are shown in Appendix F).

Figure 3.39: Dubalevu stratigraphic logs showing an 11-13 m thick surficial confining unit, composed of flood overbank deposits, overlying an intermediate confining unit of fresh interbedded siltstone and sandstone of around 10 m thickness and underlain by the fracture composite of the CS with 5-11 m thickness (Individual well logs are shown in Appendix F).

Figure 3.40: Tubakeli stratigraphic logs showing surficial confining unit, composed of flood overbank deposits overlying intermediate confining unit of fresh interbedded siltstone and sandstone and, in turn, underlain by the fracture composite of the TCR.

Figure 3.41: Bila Rd stratigraphic logs showing the surficial confining unit, composed of flood overbank deposits, a 6 m thick alluvial aquifers, comprising unconsolidated sandy gravels, which in turn are underlain by an intermediate confining unit and the fractured composite of the TF that is penetrated between 45 and 50 m in 10/4. (Individual well logs are shown in Appendix F).

Figure 3.42: well flushing of BH 10/13 at Tubakeli, Bilalevu.

Figure 3.43: installation of mono-pump in BH 10/07 at Dubalevu by MRD's drill crewmen.

Figure 3.44: test-running the mono-pump prior to constant rate test. Step-drawdown tests were not conducted at 10/07 and 10/12 due to the vibration of column pipes and preventing the free insertion and retrieval of depth probes. Hence, 10/10 and 10/11 were monitored for drawdown and recovery analysis.

Figure 3.46: TLC Solinist depth probe with stop watch, and data sheet on which drawdown and recovery data are recorded during the observation of 10/11 in response to the constant-rate pumping at 10/12.

Figure 3.45: assembling electrical submersible pump and accessories before lowering into the borehole 10/14, Bila Rd, Bilalevu.

Figure 3.47: using the volumetric method through filling up a 200 L drum and a timer, to determine the mono-pump discharge rate. Variability in discharge rate was common due to human errors and mechanical responses of pump impellers, due to kinked canvass hose and moderate suspended materials at suction level.

| Pumping well (pw) | 10/07 | 10/08 | 10/12 | 10/13 | 10/14 | 10/15 |

Table 3.6: summary of aquifer parameters derived from constant-rate pumping and recovery tests data. (Results of all tests is shown in Appendix G) Hydraulic conductivity (K) calculation for attained using the average aquifer thickness of pumping and observation wells. Storativity, where $(h_0 - h)$ and t were derived from $W(u) = 1$ and $1/u = 1$ match point, was only calculated from drawdown recorded in the available observation wells whilst the two estimates for 10/10 and 10/11 represent drawdown and recovery as they monitored full-time for drawdown and recovery analysis. BH 10/12 showing a significantly lower aquifer response during the recovery analysis suggesting that the aquifer was pumped beyond its capacity and hence, recharge is low. The pumping of 10/15 did not induce drawdown at 10/14 suggesting abundant recharge from the adjacent Sigatoka River, supported by high T and K values. Hence, the estimation of S through the use of Theiss match-curve was not made.

| Name | 31/08/10 water Level (m) | 02/10/10 water level (m) |

Table 3.7: groundwater level measured at Dubalevu. Wells 10/07, 10/08, and 10/10 are recently drilled and have not been used; 89/15/, 90/15 and 90/16 are unused irrigation sources due to non-operational mono-pumps and the others are monitoring bores. The measurements show a decline in groundwater head from August to October, which can be attributed to reduction in groundwater recharge due to low rainfall in the dry period and suggests the sensitivity of the aquifer to climatic variability.

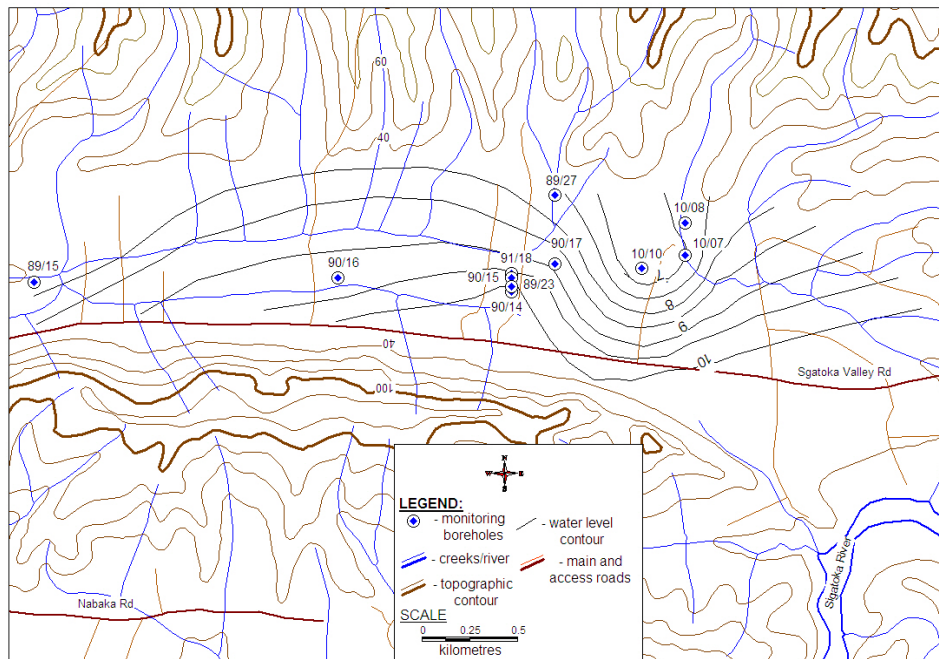

Figure 3.48: Dubalevu water level contour derived from the average of the two measurement periods and showing a NW-SE flow direction towards the Sigatoka River.

Table 3.8: groundwater level measured at Bilalevu. Five private wells, currently used for drinking purposes were monitored with measurements taken before daily pumping started to avoid any pumping effect. Wells 10/11 – 10/16 are recently drilled and have not been used. The readings showed minor fluctuations in water level from August to October. These variable responses can be attributed to complexity of groundwater flow conditions and proximity to some local recharge sources.

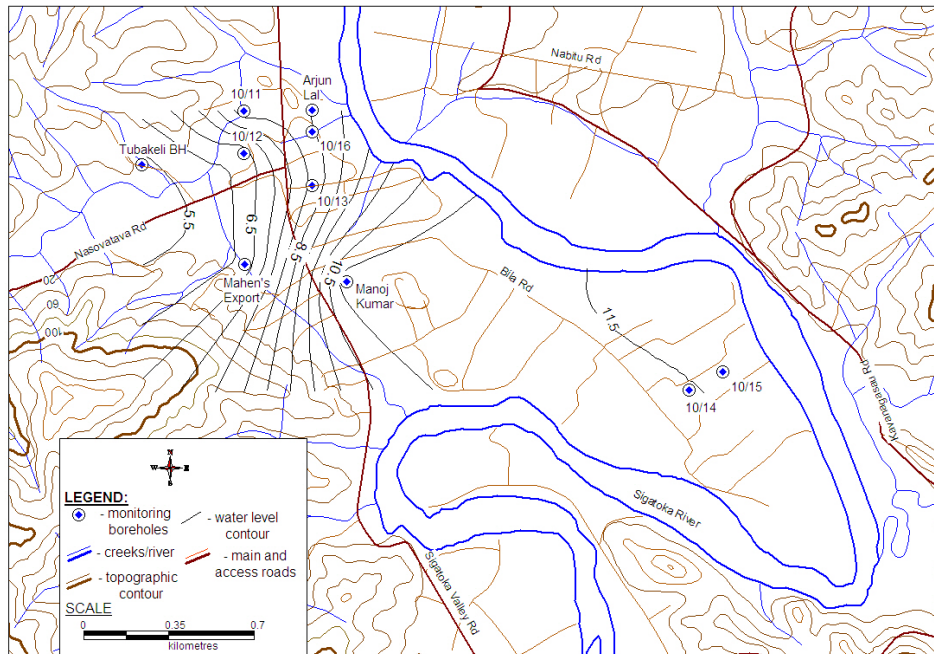

Figure 3.49: Bilalevu water level contour, taken from the averages of the two monitoring periods, showing WNW-ESE flow direction towards the Sigatoka River.

The results and interpretations presented in this section make four major contributions to the physical hydrogeology of the Middle Sigatoka Valley. First, the groundwater drilling permitted the exploration of four major hydrogeological units. These include namely surficial (silt-dominated confining units, alluvial aquifer system (unconsolidated sandy gavels), intermediate confining unit (unweathered sedimentary units) and fractured sedimentary basement. Second, pumping tests showed variable flow and storage capacities of the investigated geological units governed by primary and secondary porosities, preferential flows, heterogeneity of groundwater systems, and limited recharge. Third, the flow of groundwater towards the Sigatoka River, in both the monitored areas, suggests that river flow is composed of groundwater discharge. Fourth, the decline of groundwater level in most of the monitored wells in the two dry season months suggest that groundwater is responding to climatic conditions and hence, a relatively shallow groundwater system.

3.5 Water chemical sampling and analysis

3.5.1 Introduction

The chemical composition of groundwater is a function of bedrock composition, flow conditions and aquifer residence time (Andreo & Carrasco, 1999). This section presents the methodology and results of chemical samples collected from the study area in an effort to:

- determine the hydrochemical facies present in the study area;
- evaluate surface and groundwater interaction; and
- determine the spatial variability of groundwater chemistry and its possible causes.

3.5.2 Methodology

Forty-seven water collection sites within the study area, including groundwater, creek, river, oxbow lakes and springs, were sampled (with duplicates) from September 2009 to January 2011 for chemical analyses. Oxbow lakes, creeks, rivers, were sampled on the surface whilst springs were sampled at either discharge points or dams (Figures 3.52 & 3.54). Groundwater pumps were run to adequately purge boreholes and to allow the collection of aquifer water (Figure 3.53). Sampling site locations were determined using a Garmin 76 GPS device, whilst physico-chemical parameters, namely temperature, pH, salinity and electrical conductivity (EC) were measured using a HORIBA multi-meter probe (Figure 3.51). Samples, filled in 1 L screw-cap plastic bottles (Figure 3.54), having properly labeled and stored, were submitted to the MRD's geochemical laboratory for dissolved ionic concentration, pH, electrical conductivity, total dissolved solutes (TDS), total hardness (TH) determinations. Major ions, including calcium, magnesium, sodium, potassium, bicarbonate, sulfate and chloride, were analysed at MRD's geochemical laboratory through various analytical procedures, including titration, filtration, and colometric determination methods, adopted from the "2005 Standard for analyzing water and wastewater" (Raksha Rani, Chemist, MRD, pers.comm, 2011 Chemist, Mineral Resources Department). The results, having ionic charge balance error of less than 10% (deemed a satisfactory for hydrochemistry interpretation (Hiscock, 2005)), were input into Microsoft Excel

spreadsheets, which were later used to produce piper plots, stiff plots, contour surfaces and variability maps (Golden Software Surfer 9.0, USGS GW_chart, and MapInfo 10.0).

Table 3.11: chemical results from water sources in Nabitu (Nb), Qalimare (Q), Vunarewa (V) and Mavua (M).

Nb5, drilled to 40 m and adjacent to numerous groundwater sources, and recording relatively low pH, EC and HCO₃ suggests direction recharge from surface sources (having similar compositions to D9 and D10) as controlled by fractures systems that is hydraulically connected to the Sigatoka River. (Individual results are provided in Appendix I).

Figure 3.55: piper plots of collected chemical samples (generated in USGS GW_chart program). The samples are dominated by Ca(HCO₃)₂ type water, suggesting dissolution of calcite in the sedimentary units, with a number of samples occupying the “non-dominant type” zone, suggesting mixing from different cations sources at depths. One (1) sample, B5, showed Na(HCO₃)₂ type water with anomalously high Na⁺ concentration and suggests longer residence and limited recharge and hence, accelerating cation exchange through the saturation and precipitation of Ca²⁺ minerals and dissolution of Na⁺.

Table 3.13: chemical results from different water sources within the Bilalevu (B) area dominated by Ca(HCO₃)₂ type water except for B5 and B18, which record Na(HCO₃)₂ type groundwater. Elevated Cl⁻ B3, B9 and B18 suggest proximity to sources of chloride, such as halide or ionically enriched connate groundwater whilst the high SO₄ in B9 and 16 may represent the dissolution of gypsum along these groundwater flow paths (Individual results are provided in Appendix I).

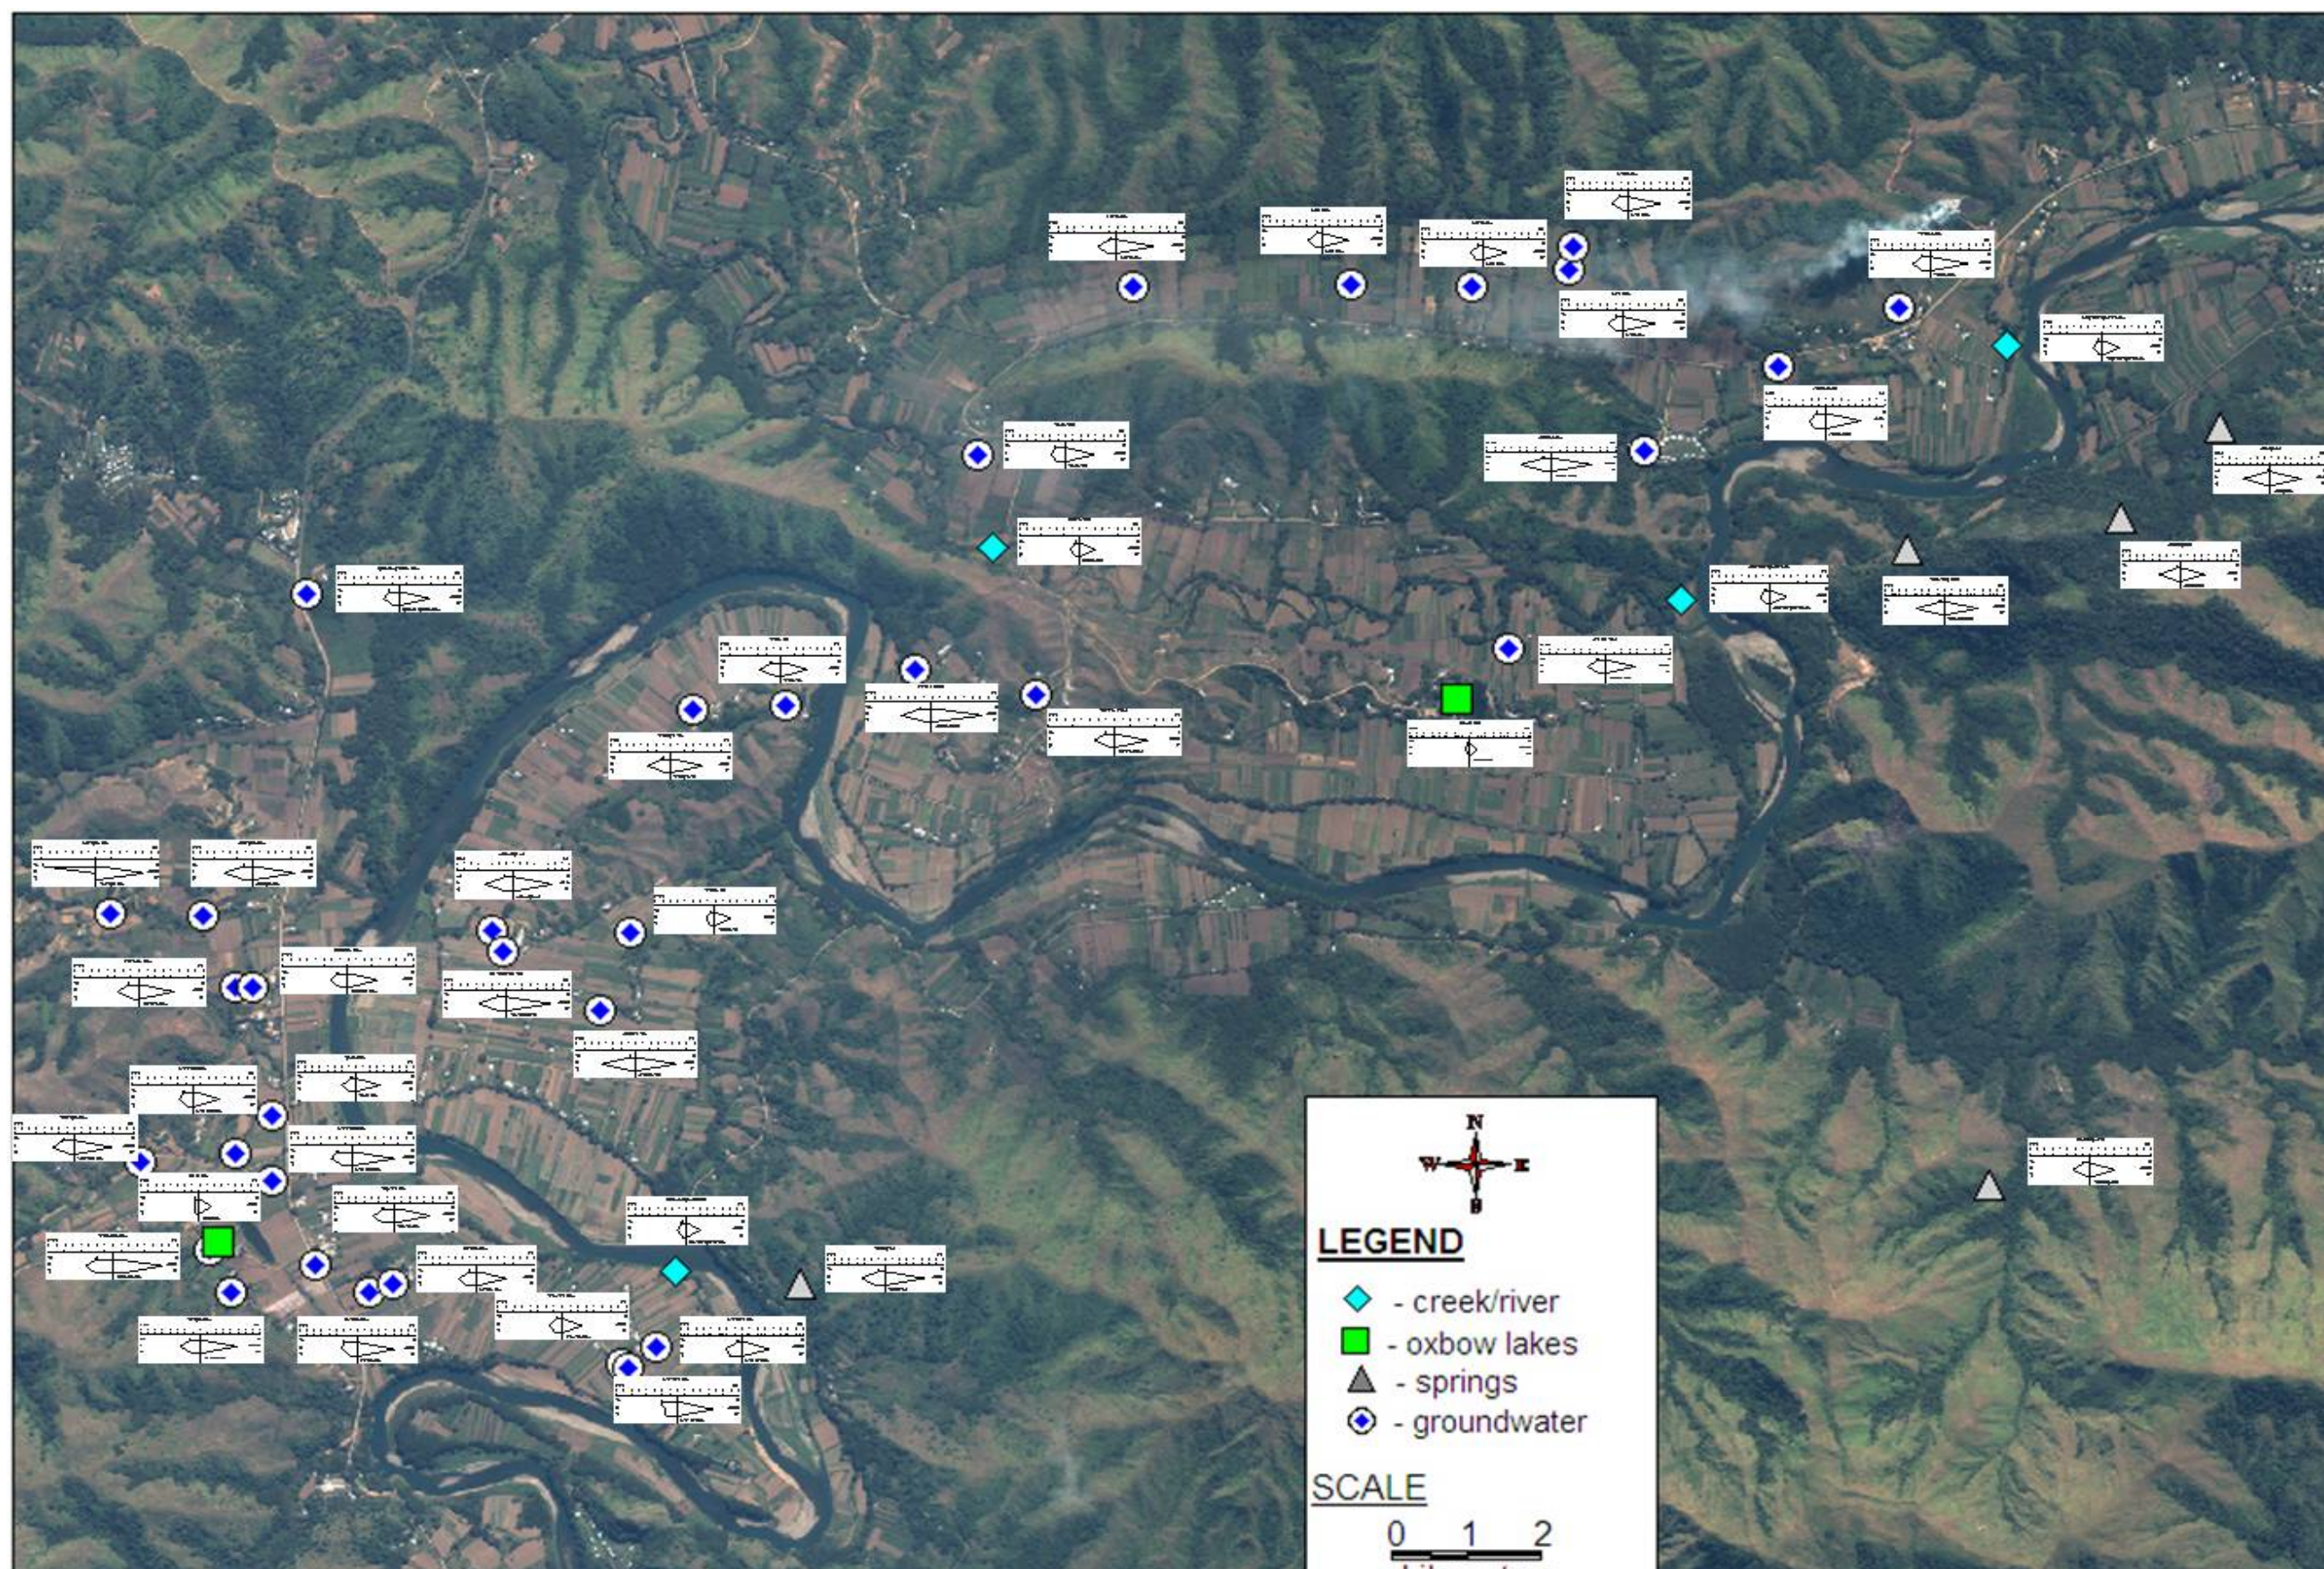

Figure 3.56: stiff plots of all collected samples showing the dominance of $\text{Ca}(\text{HCO}_3)_2$ type water with two sites (B5 and B18 recording $\text{Na}(\text{HCO}_3)$ type groundwater, The two major facies suggest variability in flow depth, travel time and recharge conditions with $\text{Ca}(\text{HCO}_3)_2$ suggesting rapid and shallow flow system with adequate flushing and recharge whilst $\text{Na}(\text{HCO}_3)$ type suggesting a deeper system and limited recharge.

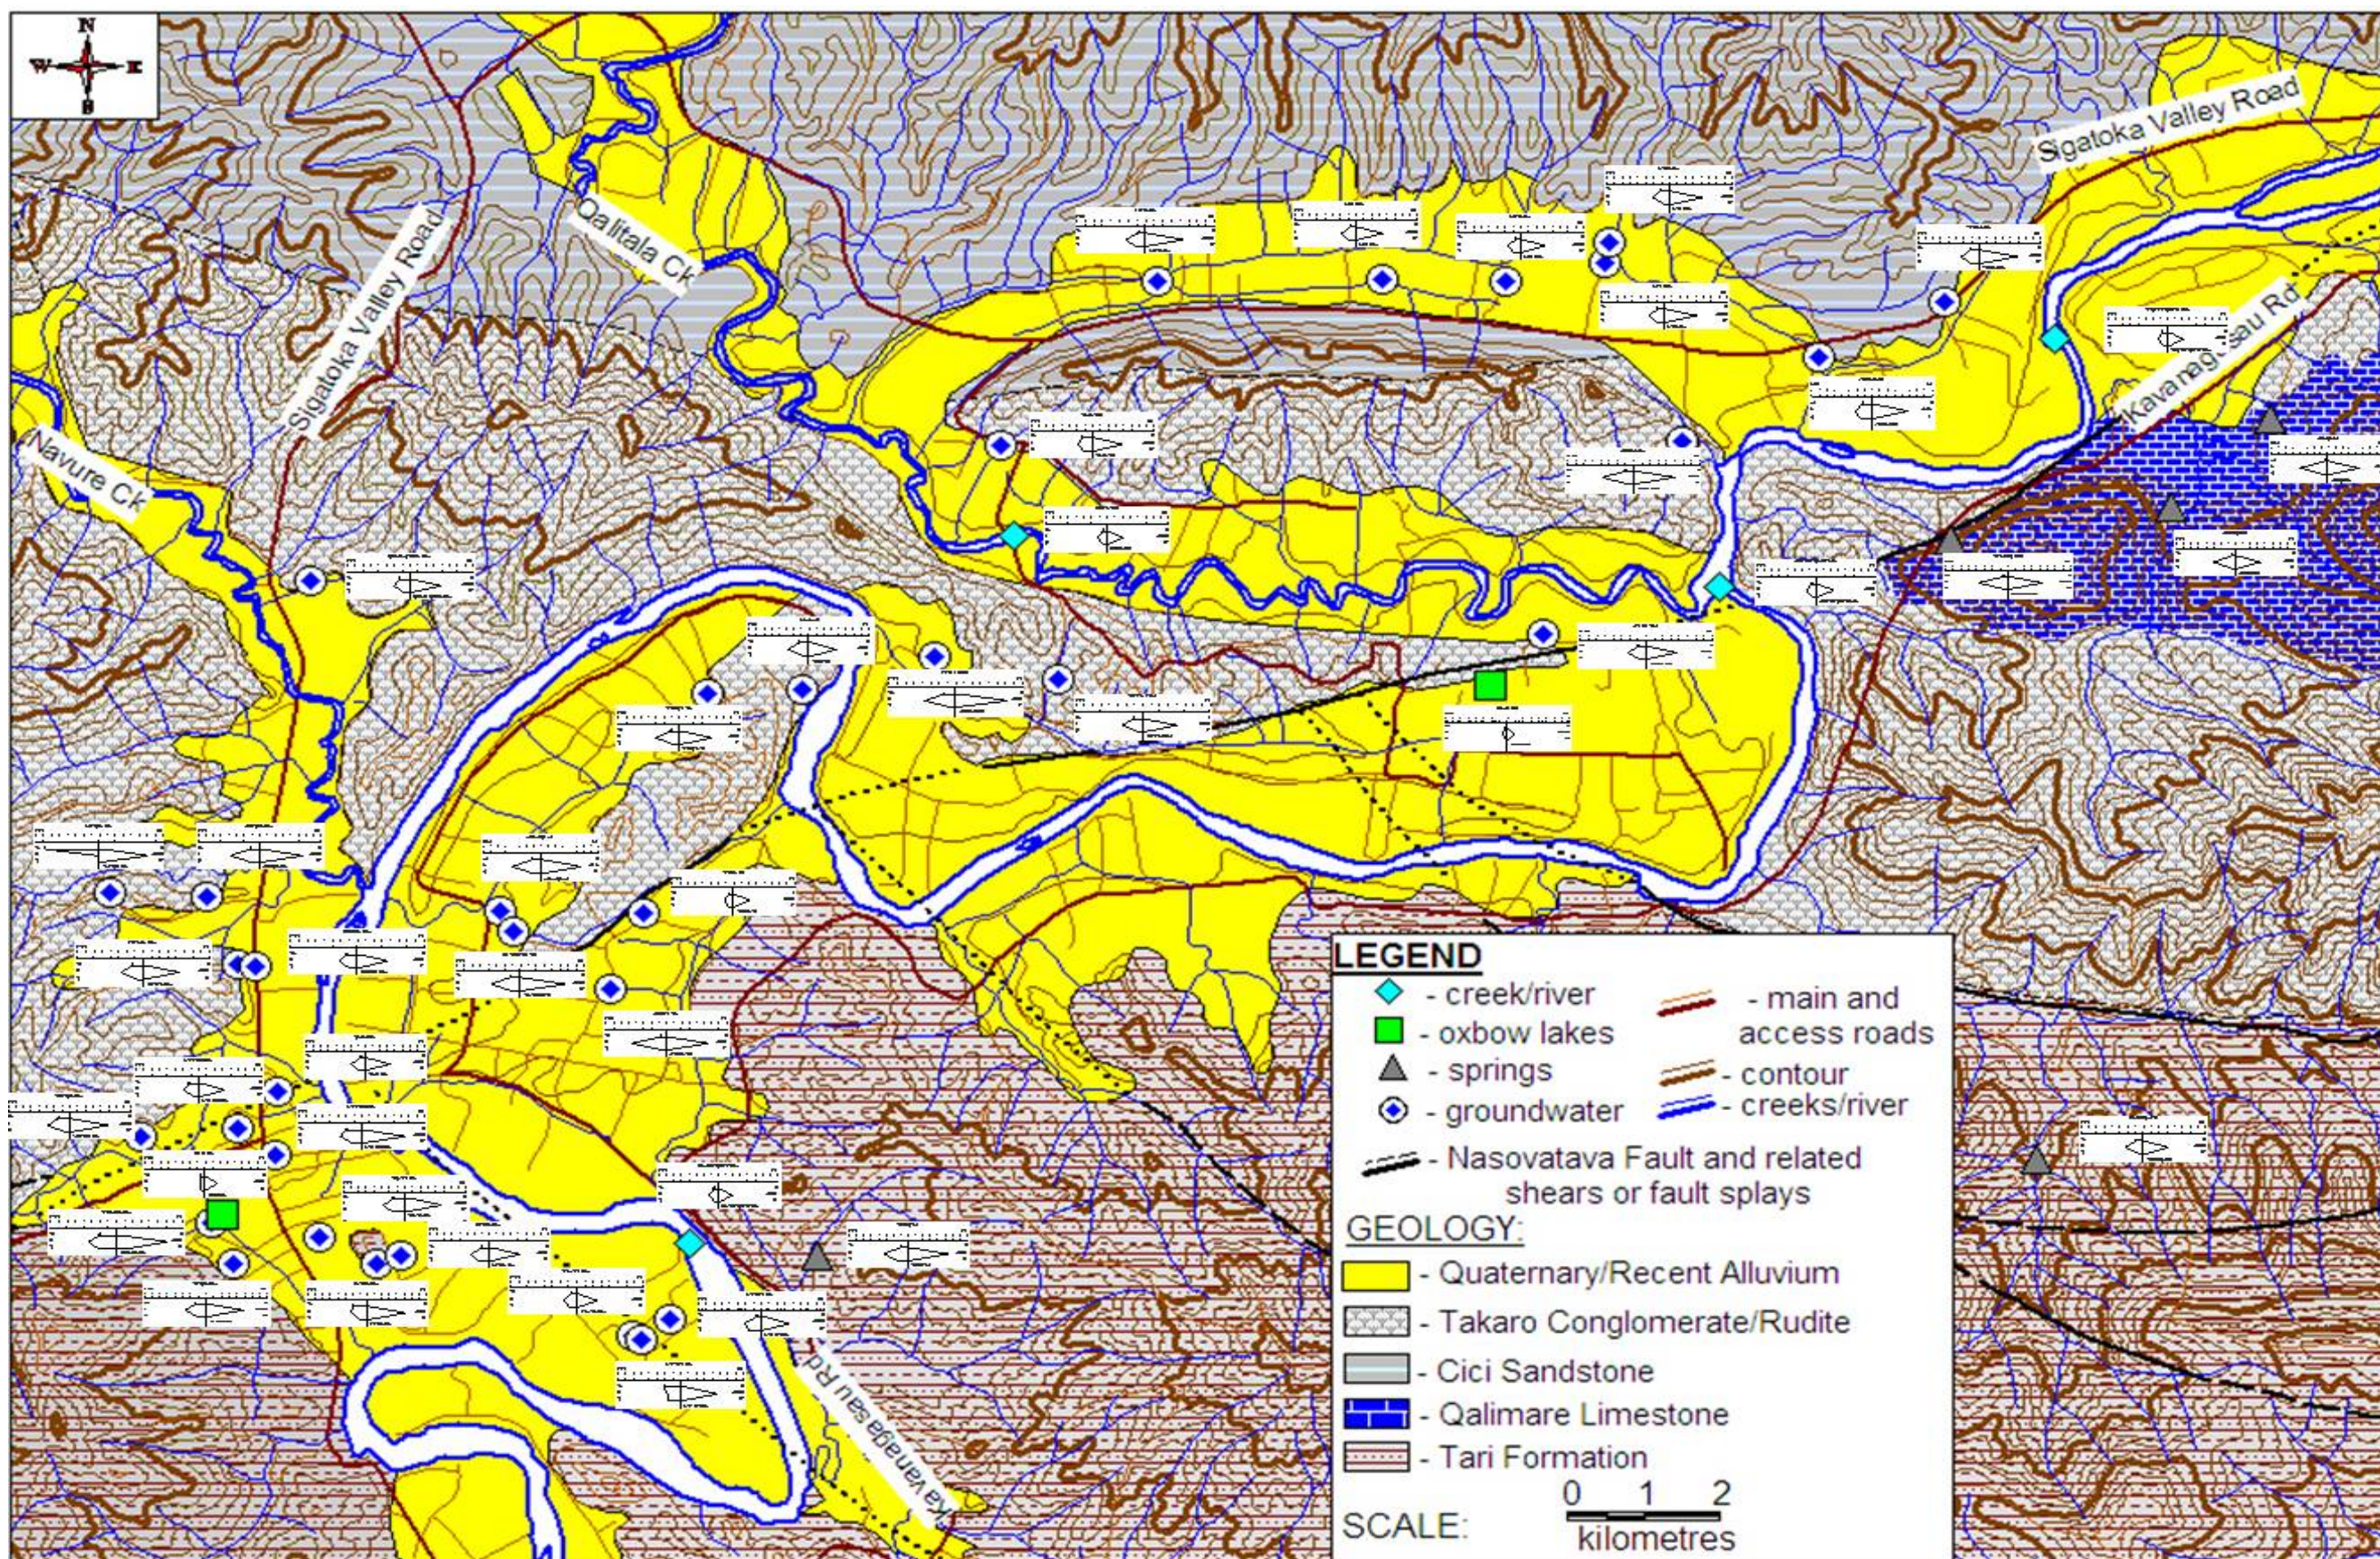

Figure 3.57: stiff plots of all collected samples superimposed on geological units and showing the dominance of $\text{Ca}(\text{HCO}_3)_2$ type water with two sites (B5 and B18 recording $\text{Na}(\text{HCO}_3)$ type groundwater across the Middle Sigatoka Valley.

Figure 3.58: plot of chloride (mg/L) vs electrical conductivity ($\mu\text{S}/\text{cm}$) showing highly variable trend.

Figure 3.60: plot of pH vs chloride (mg/L) suggesting highly variability of sources of chloride, mixing of water sources, possibly through different interconnected flow paths, hence, proves complexity of groundwater flow systems.

Figure 3.59: plot of pH vs HCO_3 (mg/L) showing highly variable trend suggesting variable flow paths, controlling varying HCO_3 exchange rates and driving the evolution of slightly acidic rainwater (pH of 5.35, Table 3.5.2) towards alkaline state.

Figure 3.61: plot of TDS vs HCO_3 (mg/L) showing linear relationship and suggesting TDS and HCO_3 will depend travel and residence, which will drive cation exchanges and ionic enrichment.

The above results and interpretations make two major contributions to the hydrochemistry in the study area. First, the catchment is composed of two major hydrochemical facies, namely $\text{Ca}(\text{HCO}_3)_2$ and $\text{Na}(\text{HCO}_3)$, and suggesting two major flow systems. $\text{Ca}(\text{HCO}_3)_2$ type waters represent shallow flow systems, rapid calcite weathering from the local sedimentary units and abundant meteoric recharge and/or flushing. $\text{Na}(\text{HCO}_3)$ type waters of relatively deep groundwater sources with more limited recharge rates and ionic (Na^+) enrichment. Second, the highly variable trends in the HCO_3 vs pH, EC vs chloride, TDS vs HCO_3 and pH vs chloride plots suggest the complexity and heterogeneity of groundwater systems as governed by variable recharge rates, HCO_3 enrichment, and proximity to some chloride sources.

3.6 Stable isotope analysis

3.6.1 Introduction

Stable hydrogen and oxygen isotopic analyses were conducted to evaluate the potential to trace waters of different compositions through the study area. These data were used to specifically determine:

- (1) if groundwater is derived from either dispersion of rapid flowing and isotopically depleted rain-derived recharge, or from slow isotopically enriched flows through fractured bedrock areal sources, and
- (2) if groundwater represent mixed meteoric and heavy isotope enriched connate water derived from basement or magmatic sources.

3.6.2 Methodology

Samples (and duplicates) were collected in air-tight 35 and 100 ml plastic vials with screw caps. Creeks, rivers and oxbow lakes were sampled at the surface whilst springs were sampled at discharge points (Figures 3.63 & 3.64). Groundwater pumps were run to purge boreholes and to permit the sampling of aquifer waters. Rainwater collectors were used to also sample rainfall in the study area, as well as in the windward area, namely Suva. Caution was taken during sample collection to keep suspended materials at minimal level to comply with NZMAF water importation guidelines after which samples were properly labeled and stored. Samples, at University of Canterbury's MAF laboratory, were extracted into 3ml screw-cap vials and properly labeled (Figures 3.65 & 3.66) before each sample was analysed three times using a Thermo Scientific Temperature conversion elemental analyser (TC/EA) to determine O^{18}/O^{16} and H^2/H^1 ratios. The TC/EA reactor is held at 1420°C and the gas chromatography column is held at 40°C with a continuous flow of ~110 ml/min of 99.9999% helium (i.e. Ultra-high purity helium). The TC/EA is connected to a Thermo Scientific Delta V Plus isotope ratio mass spectrometer (IRMS) via a Thermo Scientific ConFlo III gas distribution system. Measurement accuracy was determined through analysis of two international certified reference waters, SMOW2 and SLAP2. Measured isotopic compositions were recorded in a Microsoft Excel

spreadsheet and the average value of each triplicate sample analysis, and its corresponding duplicate, was calculated to get a realistic representation of isotopic composition, before linked to GPS-surveyed locational attributes. These were loaded into Golden Software Surfer 9.0 to generate contour surfaces and exported into compatible formats that permit its superimposition onto MapInfo 10.0 Fiji GIS system. For ease of referencing and consistency, the site IDs used for chemical sampling (refer to Table 3.9) are also used here.

3.6.3 Results

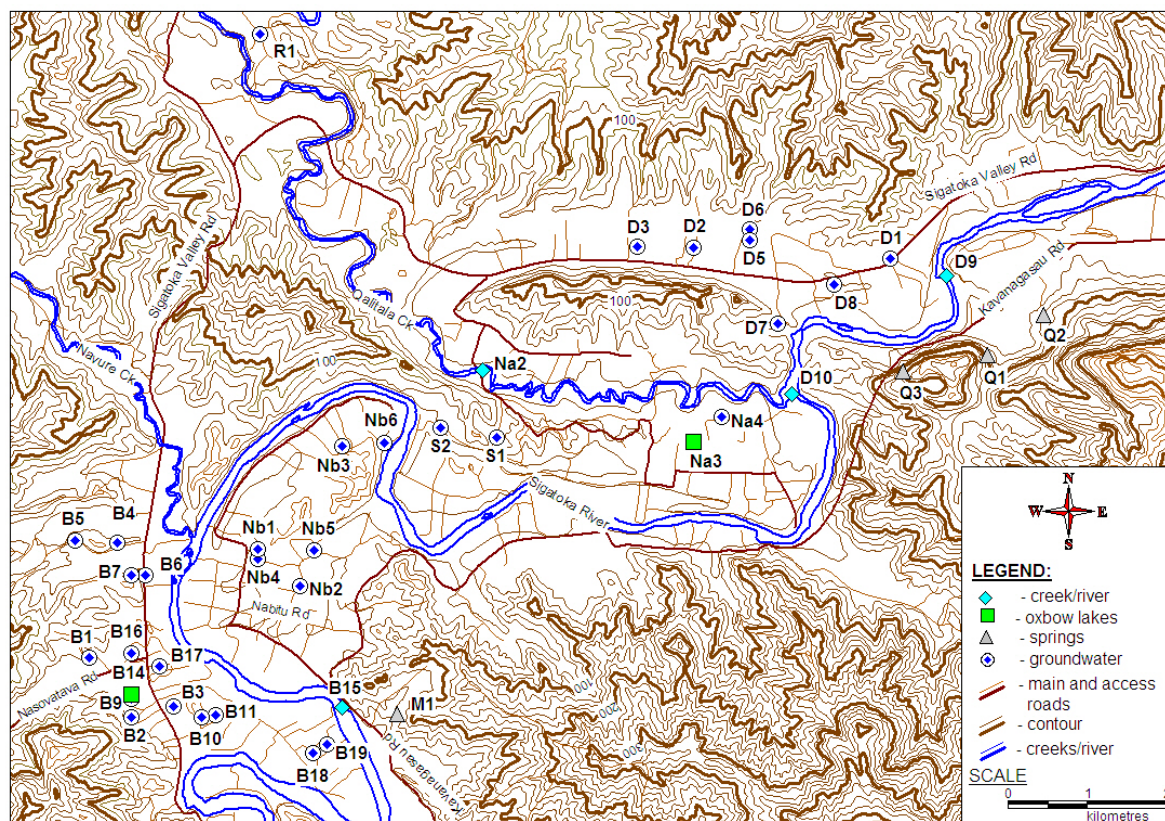

Figure 3.62 location map of isotope sampling sites with sample ID (same as chemical sampling site ID (Table 3.9). Note that D5, B16 and B19 were sampled twice (Table 3.14) whilst a number of samples were discarded due to suspended materials above NZMAF guidelines.

Figure 3.63: sample collection at Koro-i-Ra spring, a fractured spring of the Qalimare Limestone (site Q1, Figure 3.62).

Figure 3.64: Sigatoka River sample collection at the Bilalevu meander (site B15, Figure 3.62).

Figure 3.65: isotope samples, yellow capped 100 ml plastic vials, extracted into 3ml plastic vials.

Figure 3.66: labeled 3ml sample cells ready to be taken to the isotope laboratory for δD and $\delta^{18}O$ analysis.

| 10/15 | Bilalevu | 21/01/2011 | B19 | GW | -35.66 | -5.60 | 9.11 |

Table 3.14: $\delta\text{O}^{18}(\text{‰})$ and $\delta D(\text{‰})$ composition of sampled groundwater (GW), springs (SP), creek and river (ck/rv), oxbow lakes (OL) and rainfall (Rn) representing the average of samples and their corresponding duplicates with deuterium excess (d-excess) showing the variability of atmospheric conditions upon which isotope fractionation occurred (Sharp, 2007). Groundwater, with a range of -5.7 to 0.08 ‰ δO^{18} and suggesting meteoric waters flushing through the groundwater systems with variable influences of evaporation. 10/07 (D5),

showing two samples, was sampled in the 1st hour and 16th hour of long-term pumping tests. 10/12 and 10/15 (B16 & B19) were both samples during the well development and pumping test and hence, showed two samples. Rain sample (Rn1) was collected on the windward site of Viti Levu, near Suva, whilst Rn2 and Rn3 were collected at the study area (Bilalevu), in the dry and wet season, respectively.

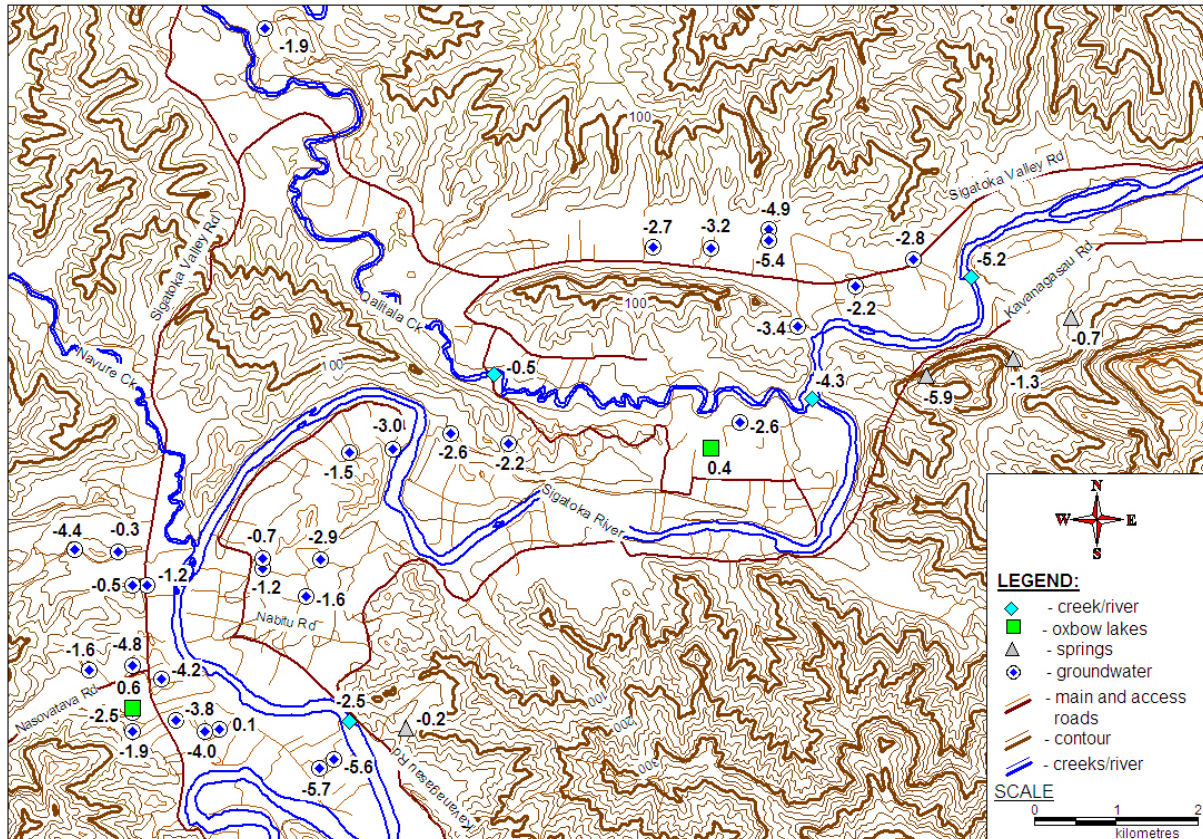

Figure 3.67: spatial variability $\delta^{18}\text{O}$ (‰) in the study area showing variable influences of evaporation on variable water sources with notable enrichment of both oxbow lakes (Na3 and B14) as well as in B11 (groundwater). NB: sites D5 and B19, having sampled twice (Table 3.14), show averages of the samples.

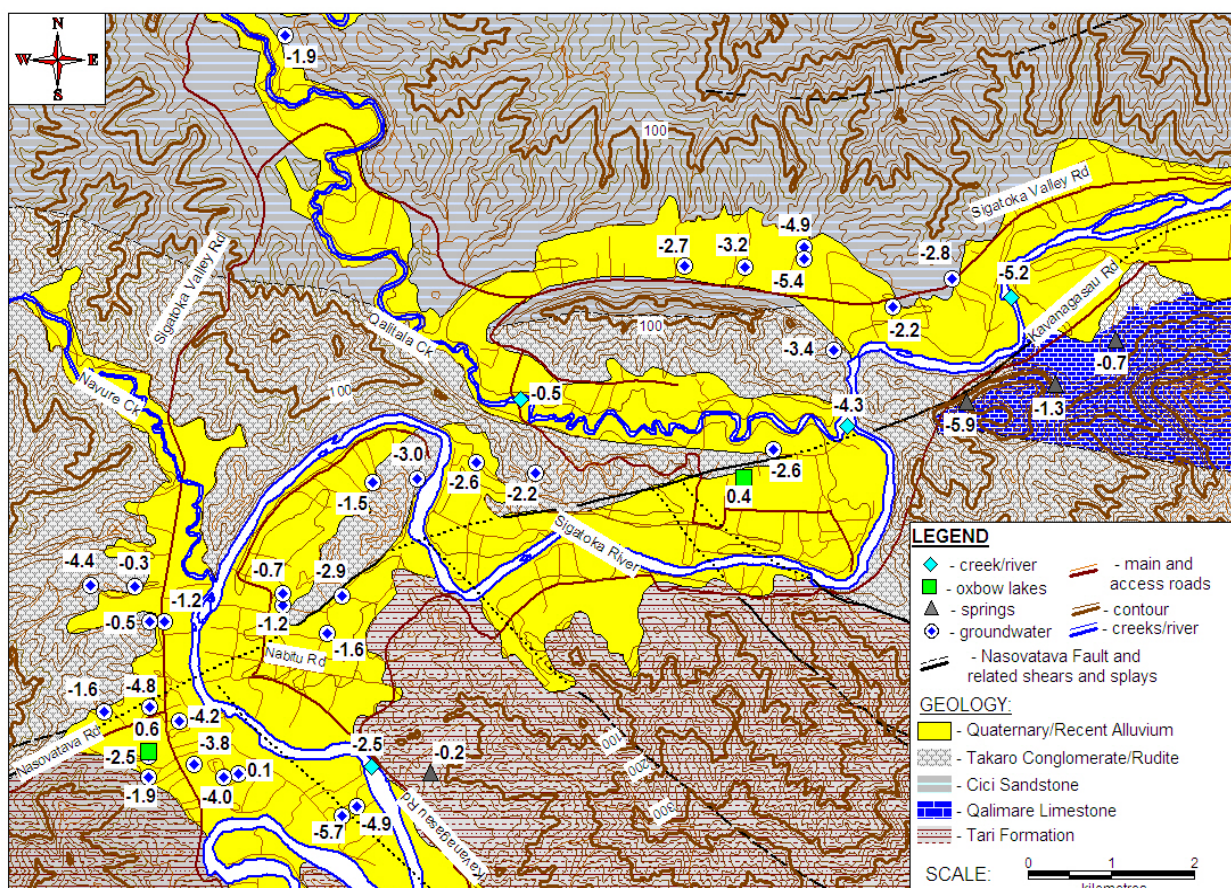

Figure 3.68: spatial variability $\delta^{18}\text{O}$ (‰) superimposed on the geological units showing variable influences of evaporation on variable water sources and aquifers with notable enrichment of both oxbow lakes (Na3 and B14) as well as in B11 (groundwater). NB: sites D5 and B19, having sampled twice (Table 3.14), show averages of the samples.

Figure 3.69: $\delta^{18}\text{O}$ (‰) vs δD (‰) plot of water sources in the Middle Sigatoka Valley plotting on a LMWL slope of 4.3 in relation to the GMWL of relation $\delta\text{D} = 8 \times (\delta^{18}\text{O}) + 10$.

Figure 3.70: $\delta^{18}\text{O}$ (‰) vs δD (‰) plot of groundwater and springs in the study area together with groundwater and springs data documented in Cox and Hulston (1980) in relation to GMWL of relation $\delta\text{D}(\text{‰}) = 8 \delta^{18}\text{O} (\text{‰}) + 10$. Clearly, the more negative isotope values are plotted close to the GMWL, suggesting recent meteoric waters whilst variable influences of evaporation is causing a more positive linear trend that is falling away from the GMWL with a slope of 4.34 for the Middle Sigatoka Valley samples in relation to a slope of around 6.5 for 1980 data.

Figure 3.71: $\delta^{18}\text{O}$ (‰) vs δD (‰) plot of surface sources, namely creeks, rivers, oxbow lakes and rain for this research, and surface sources sampled in 1980 (Cox & Hulston, 1980) in relation to GMWL of relation $\delta\text{D}(\text{‰}) = 8 \delta^{18}\text{O} (\text{‰}) + 10$. The water resources in the study area plot along the leeward side evaporation line of slope 4.34, while the windward sources fall on or close to the GML. Variability in isotopic composition of rainwater collected in the study area (Rn2 and Rn3) suggest isotopically depleted waters precipitating (possibly from higher altitude clouds) during dry season (due to high evaporation and low humidity) whilst isotropic enrichment in the wet season can be attributed to Rayleigh isotopic effect causing the preferential precipitation of heavy isotopes (Sharp, 2007). Rainwater samples, Rn1 and Rn3, showed similar isotopic signature and suggests variable atmospheric conditions.

Figure 3.72: $\delta^{18}\text{O}$ (‰) vs HCO_3 plot of sampled water sources showing highly variable pattern of bicarbonate exchange with respect to depletion or enrichment of $\delta^{18}\text{O}$.

The above results and interpretations make four major contributions to the hydrochemistry of the study area. First, the linear trend of predominantly negative and relatively positive isotopic compositions, along a local meteoric water line (LMWL) of slope 4.3, suggest that water resources are meteoric in origin with variable modifications by evaporation and mixing with other residual evaporated waters in surface and groundwater storage. Second, the comparative analysis of the study area with the previous isotopic survey data collected in Vanua Levu and Viti Levu showed similarities in more negative isotopic characteristics with a number of previously sampled leeward sources plotting close the study area data, which suggests similar atmospheric conditions. Third, the Sigatoka catchment showed lower LMWL slope in relation to the 1980 LMWL, which can be attributed to the valley's leeward and more arid climatic conditions. Fourth, the highly variable HCO_3 and $\delta^{18}\text{O}$ plot suggests variable bicarbonate enrichment and variable modifications from evaporation occurring at different water sources, particularly in groundwater sources, and hence, signifies the complexity and heterogeneity of subsurface flow systems.

3.7 Chloride concentration test

3.7.1 Introduction

This section presents the methodology and results of chloride concentration test conducted on collected isotope samples to determine the spatial variability of chloride in the sampled water sources.

3.7.2 Methodology

Following the extraction of 3ml isotope samples (Section 3.6), the remaining sampled waters, were analysed for chloride concentration. Two (2) 20 ml screw-cap plastic cells, namely blank and sample, were filled with 10 ml of sample waters. The blank cell was closed and ready for testing while different chloride tablets were added into sample cell. One (1) RT-120 chloride acidifying tablet was added and mixed to dissolve in the sample cell before one (1) RT-121 Chloride tablet was added (without crushing or mixing) and allowed to disintegrate for 2 minutes to produce a murky solution (Figure 3.73). Both the blank and sample cells were then slotted in the “Model 975 MP Analyst” from Orbecco-Hellige (Figure 3.74): a portable micro-processor based water analysis system was used to read the chloride concentration in mg/L . Test 34 was selected in the equipment whilst the filter was set to 528 nm as per test procedure manual. Both the blank and samples cells were slotted into the Analyst reader for Cl^- concentration measurement.

3.7.3 Results

Figure 3.73: remaining sample (left) and blank (right) cells after chloride tablets have been added in the sample cell producing murky colour.

Figure 3.74: the Model 975 MP Analyst with a blank (right) and sample (left with cloudy appearance) cells ready to be slotted for Cl^- concentration measurement (mg/L).

Table 3.15: chloride concentration (mg/L) of collected isotope samples. The results, dominated by low [Cl⁻] (1.02-18.3 mg/L), suggest either recharge-induced dilution or short travel paths preventing accumulation of [Cl⁻]. Elevated [Cl⁻] at three (3) sites (with >30 mg/L concentration), suggesting proximity to some chloride sources. The low chloride (<40 mg/L) concentration, together with isotopically depleted water, suggests that all sampled water sources are mainly meteoric in origin. D5, collected the 1st and 16th hour of pumping tests, showed variable [Cl⁻]. The variability in [Cl⁻] in the Bilalevu rainwater samples, Rn2 and Rn3, collected in dry and wet seasons, suggest the variable source of solute, probably caused by difference in precipitation altitude in the seasons. Similar [Cl⁻] concentration between rainwater collected in Rn1 (windward area) and Rn3 suggests similar atmospheric conditions.

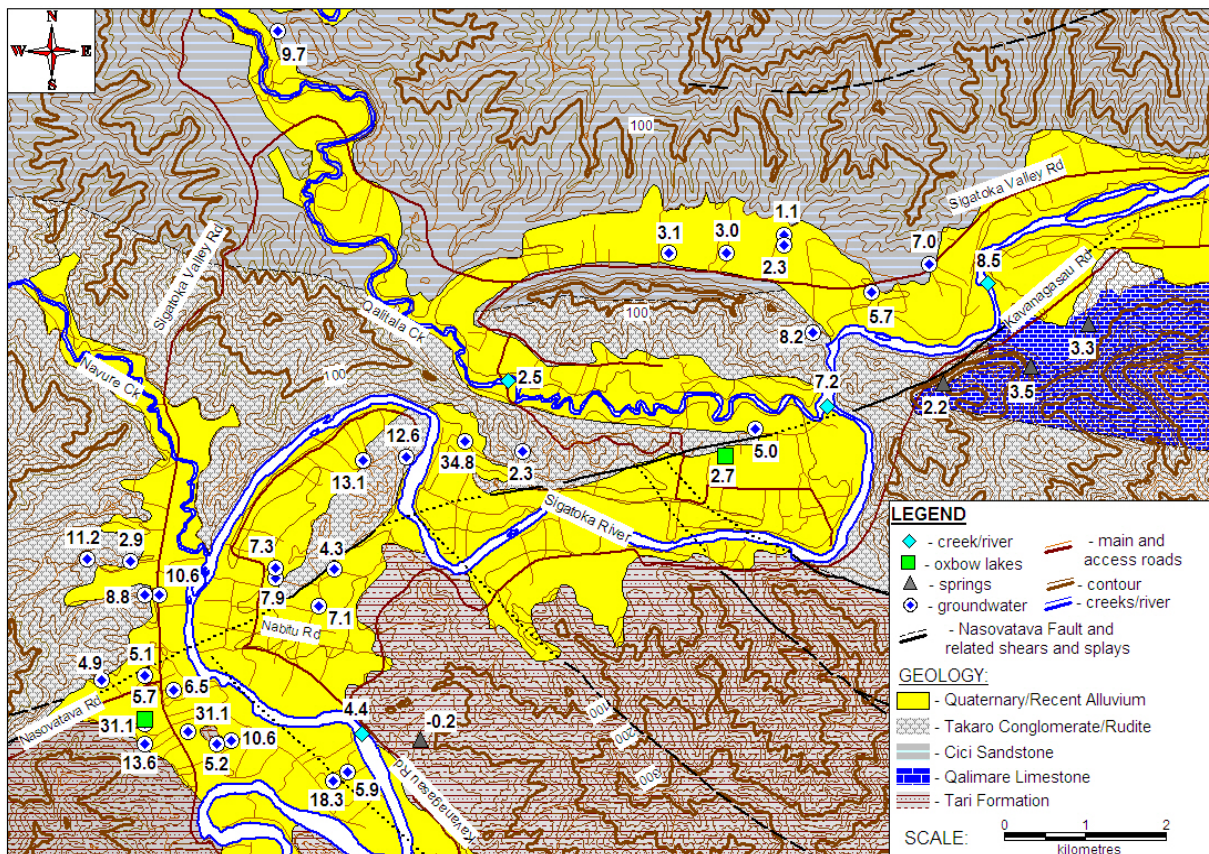

Figure 3.75: chloride spatial variability superimposed on geological units showing predominantly low $[Cl^-]$ (1-18 mg/L) with three areas of elevated concentration and suggesting proximity of some $[Cl^-]$ sources. The dominant low $[Cl^-]$, together with the isotopically depleted compositions, suggests abundant meteoric recharge-induced dilution.

Figure 3.76: plot of $\delta^{18}O$ vs chloride (mg/L) dominated by isotopic depletion and low $[Cl^-]$ (0-20 mg/L) suggests minimal accumulation of $[Cl^-]$ along flow paths suggesting either short recharge to discharge ($R \rightarrow D$) travel path or abundant and rapid recharge-induced dilution. Elevated $[Cl^-]$ in sites S2, B3 and B9, suggest proximity to some chloride sources. $[Cl^-]$ variability in rainwater measured in the study area (sample Rn2 and Rn suggest different sources of air

masses and solutes with the dry season rain event (R2) likely to be sourced from high altitude airmass from a distal source that may have lost most of its chloride before reaching the study area whereas the wet season rainfall event (Rn3) may represent low altitude airmass that is saturated with solutes from a nearby source (local). Similar isotopic compositions and $[Cl^-]$ of Rn1 and Rn3 suggest similar sources of solute and atmospheric conditions of precipitation.

Figure 3.77: plot of depth of water source vs chloride concentration showing highly scattered data, particularly for groundwater sources, suggesting variability of $[Cl^-]$ sources with depth. Low chloride concentration suggests either short R→D travel path or recharge-induced dilution whilst slight elevated $[Cl^-]$ measurements may suggest proximity to $[Cl^-]$ sources, such as halite and ionically enriched connate groundwater.

The results and interpretation make four contributions to the hydrochemistry of the Middle Sigatoka Valley. First, the predominant low chloride suggests abundant meteoric recharge to cause adequate dilution of the water sources as supported by the relatively negative isotope characteristic. Second, the low chloride concentration eliminates the possibility of magmatic mixing in the investigated hydrogeological system. Third, the highly variable low chloride and depth source, particularly with groundwater, suggest that shallow flow system and short travel time to prevent chloride accumulation. Fourth, the chloride variability and isotopic composition of the sampled rain events can be attributed kinetic and Rayleigh isotopic fractionation prevalent in the different seasonal climatic conditions, as well as the proximity of the solute sources in the air mass.

3.8 Groundwater recharge

3.7.1 Introduction

The growing demand and use of groundwater resources, particularly during the dry season, represents a major human impact that may jeopardize the safety, equitable allocation and sustainability of groundwater resources. This section presents the methodology and results of a water resources inventory, including physical and chemical mass balance models to:

- determine groundwater recharge rate; and
- establish sustainability of groundwater resource.

3.7.2 Methodology

Owners and pump attendants of privately drilled wells (within the 40 km² study area) interviewed for well details, including depth, abstraction rate, duration to establish the amount of groundwater abstraction for drinking and irrigation purposes (Table 3.16). The Ministry of Agriculture's irrigation profile was reviewed for irrigation data using low-lift pumps for sprinkler irrigation systems within the study area (Table 3.17) whilst the long-term rainfall and evapotranspiration of the Sigatoka area was documented in Hawaiian Agronomics International Inc (1984). Runoff studies in the SW Viti Levu, conducted in forested and grassland range from 2.7-5.5% of rainfall, was estimated at 4.1% of total rainfall (Waterloo et.al., 2007). The calculation of the water balance is made upon the following assumptions:

- groundwater abstraction during the wet season is solely for drinking purpose whilst it is utilized for both irrigation and drinking purposes in the dry season;
- irrigation is only conducted during dry months; and

With the available data, the physical water balance is calculated through the equation:

$$R = P - (ET + Ru + GA) \text{ (for wet season)}$$

$$R = (P + I) - (ET + Ru + GA) \text{ (for dry season)}$$

where R is recharge (m³/month), P is precipitation (m³/month), I is irrigation (m³/month), ET is evapotranspiration (m³/month), Ru is runoff (m), GA is groundwater abstraction (m³/month).

Chloride mass balance (CMB) equation, applicable for alluvial aquifers to determine recharge (Kresse & Clark, 2008), was also used through the following formula:

$$R = P * C_p / C_{gw}$$

where R is recharge (m/month), P is precipitation (m/month), C_p is chloride concentration in precipitation (mg/L), and C_{gw} is chloride concentration in groundwater (mg/L).

Chloride concentrations of two rainfall samples collected at Bilalevu were measured through chloride concentration test (Chapter 3.7). The dry season rainfall event was sampled on August 31st, 2010 whilst the wet season rainfall event was collected on November 25th, 2010. For the alluvial aquifers, chloride concentration of three sites sampled in both the climatic seasons, namely D3, D4 and B8, was used. Well B8, penetrating a silty sand aquifer at Bilalevu, was sampled on October 6th, 2009 and while both D3 and D4, occurring in unconsolidated sandy gravels at Dubalevu, were sampled September 1st, 2009 during the dry period. All these aquifers were sampled on January 28th, 2010 during the wet season (refer to Figures 3.5.1 and 3.6.1 for the locations of these alluvial aquifers).

3.7.3 Results

| Total irrigation (m ³ /month) | - | 83883.6 |
| Total Recharge (m ³ /month) | 3018951.13 | -440450.90 |
| Total Recharge (m/month) | 0.08 | -0.01 |

Table 3.18: physical water balance recharge calculation showing 0.08 m/month in the wet season (which is a 36% of monthly rainfall) and a recharge deficit of -0.01 m/month (details of the calculations are shown in Appendix H).

| Season | Wet | Dry |
|--------------------------------|-------|------|
| Precipitation (m/month) | 0.223 | 0.89 |
| Chloride (mg/L) | | |
| Rain | 5.84 | 1.06 |
| B8 | 6.65 | 9.75 |
| D4 | 2.22 | 5.98 |
| D3 | 3.99 | 4.43 |
| Recharge (m/month) | | |
| B8 | 0.19 | 0.10 |
| D4 | 0.58 | 0.16 |
| D3 | 0.33 | 0.21 |

Table 3.19: groundwater recharge estimate of 0.19 – 0.59 m/m⁻¹ in the wet season and 0.1 – 0.21 m/m⁻¹ in the dry season. Chloride concentration represent 31/08/10 and 25/11/10 rainfall events whilst alluvial aquifers samples from wells B8, D4 and D3 were collected in September/October 2009 and January 2010 (refer to sample AL09/03, AL09/04, AL 09/10, AL10/06, AL10/10, and AL10/11 in Appendix I). Chloride concentration is higher in dry season due to evaporation-induced Cl⁻ enrichment whilst abundant recharge-induced dilution is observed during the wet season. B8, drilled in to a silty sand aquifer, recorded slight lower recharge as opposed to D3 and D4, which occur in unconsolidated sandy gravels.

The above physical and chemical models make three contributions to the groundwater recharge mechanisms at the study area. First, two major recharge mechanisms can be established. The fractured sedimentary units, from which most of the drinking wells are sourced, are recharged by rainfall that is flowing through preferential pathways in the fractured systems, whilst alluvial aquifers are recharged by leakage of adjacent surface sources that is rapidly dispersing through unconsolidated macro-pores. Second, rainfall recharge, through physical model, is constrained by climatic variability as shown by the recharge surplus and negative replenishment in the wet and dry seasons, respectively. Third, the sustained recharge rates, estimated from the chemical model, suggest that the hydraulic connectivity of the alluvial systems to the surfaces water sources will warrant continued recharge. The fluctuating recharge rates in the wet and dry season are likely to be related to seasonally variable surface flow conditions.

4.0 DISCUSSION

This chapter examines and integrates the results, presented in chapter 3, in an attempt to define and classify the underlying hydrogeological system present in the Middle Sigatoka Valley (MSV). The following sections include a discussion of the interpretation of geophysical data, physical hydrogeology, hydrochemical facies identification and groundwater recharge estimates from mass balance modeling.

4.1 Interpretation of the geophysical data

Geophysical survey results demonstrate high resolution vertical and lateral variability in geophysical properties, namely electrical resistivity and electro-magnetism. Thus, suggesting heterogeneity in the physical and chemical properties of the geological and hydrogeological materials. The dipole-dipole strong gradient (DDSG) array profiles generated a detailed dataset in relation to the smoothed Schlumberger profiles (Appendix 2.1). The electromagnetic (EM) results, presented as a tapered 5-point running mean, showed features of high lateral and vertical variability in electromagnetic properties. Most of this variance is supported by the electrical resistivity (ER) models. The following sections will focus on the DDSG and tapered EM data and analyze these results as per these pre-survey objectives:

- to show water table depth, determine maximum thickness and spatial extent of alluvium materials;
- to estimate depth to bedrock;
- to identify subsurface anomalous structural features, such as folds, fracture density and faults, which are propitious for groundwater flow and storage; and
- to select potential drill sites.

4.11 Depth to water table, thickness and infilling behavior of alluvium materials

Overall, delineation of water table (Tables 3.2 & 3.3) was difficult in all survey areas due to the saturation of the capping soil from high rainfall associated with Tropical Cyclone Mick (TCM)

whilst the infilling alluvium appears to be constrained by either deformed, uplifted or incised bedrock. As shown below in Figure 4.1, fluvial deposits at Dubalevu are characterized by low resistivities and are ~3-8 m thickness in the first 100 line positions. These units increase in thickness, to ~10-16 m, beyond 120 m survey line position. No buried river gravels, that would be expressed as a high resistivity zone within the low resistivity zone (i.e. between 0-16 m depths), was observed. These results suggest that the Dubalevu survey area is dominated by overbank deposits of relatively uniform grain size and composition.

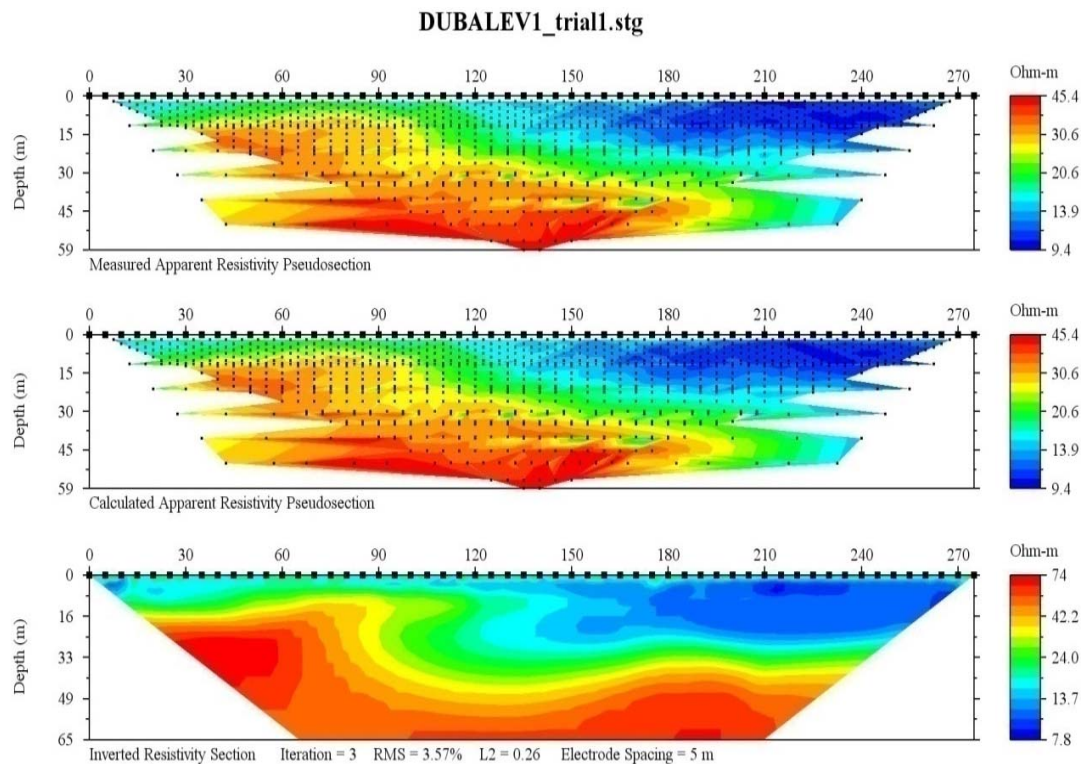

Figure 4.1: resistivity (DDSG array) profile at Dubalevu.

Figure 4.2: horizontal dipole response showing a uniform increase in EM responses beyond 100 m reading positions at Dubalevu.

Figure 4.3: vertical dipole response at Dubalevu show a noisy dataset with uniform peak responses between 240-280 m reading positions

An increase in conductivity responses, in Figures 4.2 and 4.3, beyond 100 m EM line positions results from the increasing thickness of saturated alluvium estimated at 7.5-15 m thickness as shown from 10-m coil separation responses in this area. The relatively low horizontal dipole (HD) response is indicative of compact and dry overbank silt whereas the high vertical dipole

(VD) response, due to its deeper depth penetration (Table 3.1), is likely to be caused by increased pore spaces and water content and may represent either pebbly silts or weathered basement at 15 m depth

At Tubakeli, the resistivity profile shown below (Figure 4.4) exhibited an extensive and low-intermediate resistivity layer around 4-7 m depth suggesting flood overbank materials, namely silt and fine sand dominate the shallow subsurface. A low resistivity zone ~8-20 m depths, together with patches of very low response between 0-30 m and 150-180 m resistivity line positions, could represent either saturated overbank materials from excess infiltration from the cyclone event or weathered bedrock. The saturated overbank interpretation is supported by relatively uniform 10-m horizontal and vertical dipole responses (Figures 4.4 and 4.5), suggesting fine and compact materials.

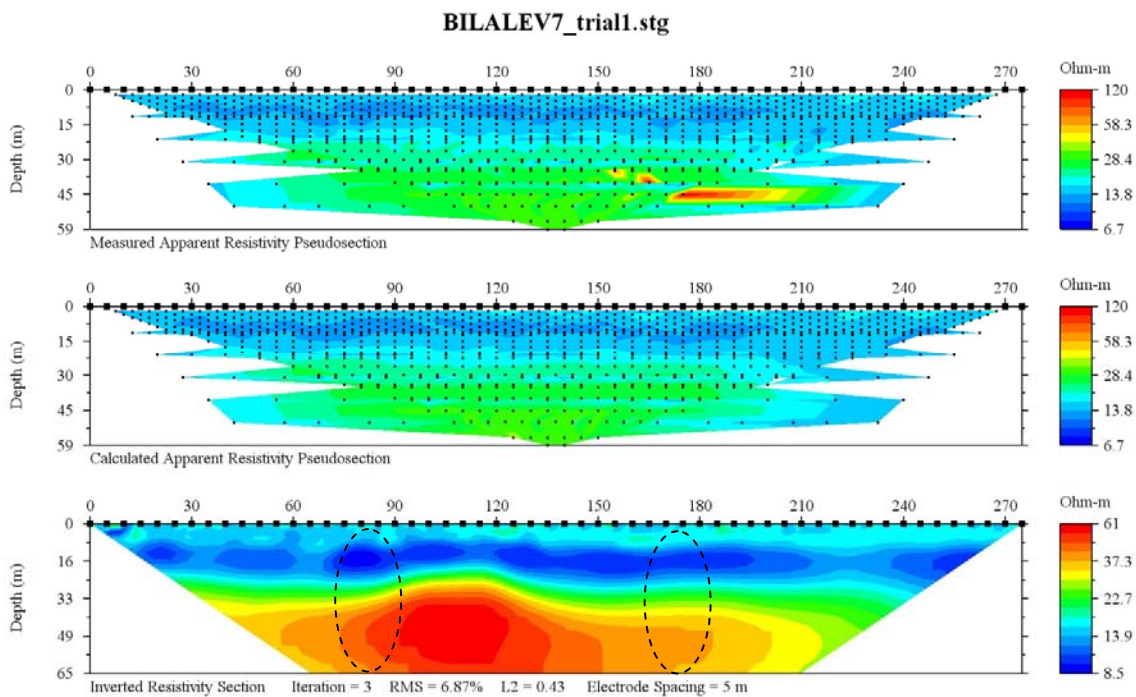

Figure 4.4: resistivity (DDSG array) from Tubakeli showing zone high resistivity from 40-65 m depths (possibly bedrock) and surrounded intermediate resistive zone, suggesting weathered or fractured composited. Areas low resistivity may indicated saturated overbank flood deposits. The dashed oval represent areas of possible fractured systems as shown by 20-m VD peaks at Figure 4.5.

Figure 4.5: EM line 2 horizontal dipole response at Tubakeli showing relatively uniform response in both coil separations with a higher 20-m separation response suggest slight altered porosity at around 15 m depth.

Figure 4.6: EM line 2 vertical dipole response at Tubakeli showing fluctuating responses of 20-m separation and suggests presense of possible fractured system around 35 m depth between 60-100 m and 150-180 m EM positions.

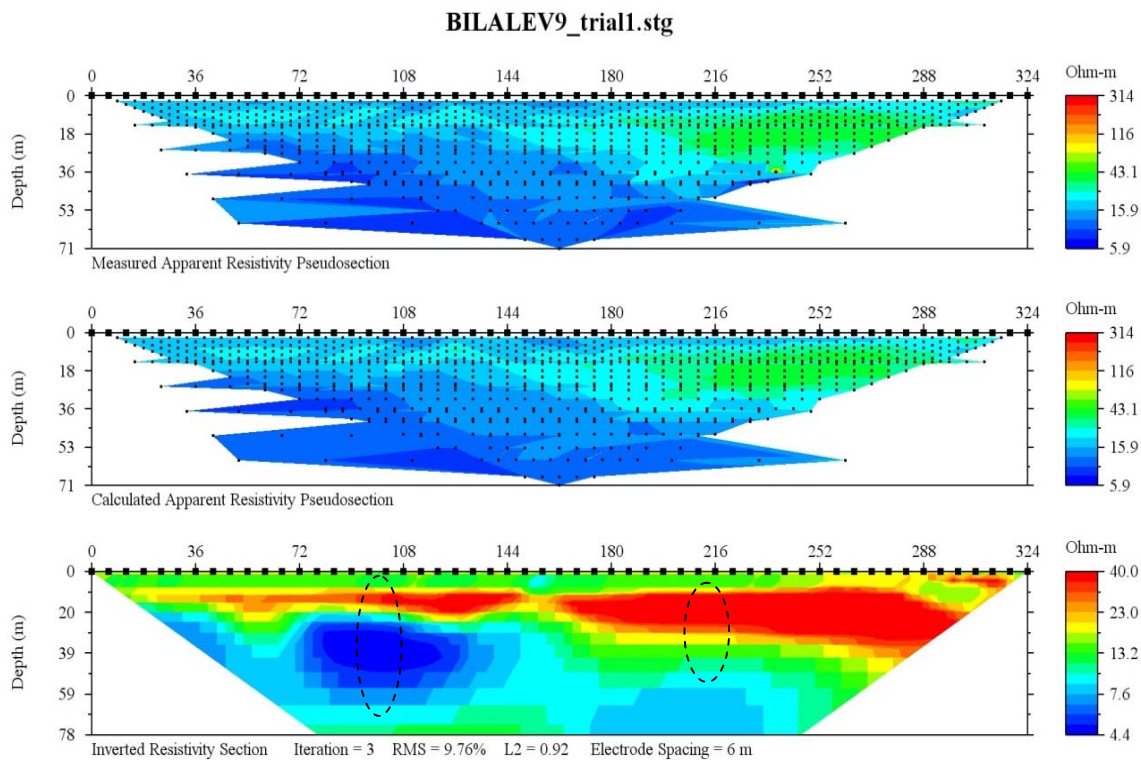

Figure 4.7: resistivity profile at Sugar Ram's farm at Bila Rd showing a possible sheared bedrock at 28-48 m depths between 72-110 m ER positions together with an inferred gravel bar characterised by very resistive zone around 10-20 m depths.

Figure 4.8: horizontal dipole EM response at Bila Rd, Bilalevu showing a relatively high response of 20-m separation suggesting altered porosity at 15m depths whilst the decreasing responses of all coil separations towards the end suggests the influence of the buried gravels bar in attenuating the emitted signals.

Figure 4.9: vertical dipole EM response at Bila Rd showing a noisy dataset with higher response of 20-m and 40-m separations supporting the the presence the sheared bedrock between 35-60 m depth, while the decreasing trend towards towards the end of the line suggests the influence of the inferred gravel bar attenuating all the emitted electric current and hence, inducing low EM response for all coil separation. Two potential drill sites, denoted by dashed ovals, have been selected.

At Bila Rd (Figure 4.7), the top 0-8m depths appears as a low resistivity zone and suggests saturated flood overbank silts and fine sand from TCM excess rain. This is, again, supported by 10-m HD showing low response in the first 120 m positions, suggesting silty materials at around 7.5 m depth. Resistivity profiles from around 100 m ER line positions show a distinct band of high resistivity (> 30 ohm-m) with a maximum thickness of around 8-10 m between positions 100 – 300 m (10–20 m depth) and tapers to around 3 m between 70-90 m (10-13 m depth). This could represent an unconsolidated gravel bar, potentially a buried paleo-Sigatoka River course, that is hydraulically connected to the present river course and hence, could be a favorable groundwater source. Electromagnetic responses support this hydraulic connectivity interpretation (Figures 4.8 & 4.9) with a decreasing trend towards the river where the resistive gravel bar yields low responses between 120-340 survey positions.

4.12 Depth to bedrock

Figure 4.1 clearly shows the depth to the deformed Cici Sandstone (CS) at Dubalevu, characterized by the undulating basement with high resistivity (29-74 ohm-m) and a weathered-mantle (moderate resistivity of 20-29 ohm-m). A bedrock high, probably at 8-15 m depth, is

represented by high ER and low EM responses within the first 100 m positions (Figures 4.2 & 4.3). An increasing depth to bedrock is noticeable in the resistivity profiles from 100-270 m ER line positions and is supported by a gradual increase in conductivity responses from 100 m EM position for all coil separations and orientations. These can be attributed to either increasing depth to bedrock or increasing thickness of saturated alluvium or both. At Tubakeli, the depth to the Takaro Conglomerate/Rudite (TCR) can be estimated at 20-23 m with a low dip towards North. Figure 4.4 showed bedrock as heterogeneous with a high-intermediate resistivity core, around 100-180 m and 90-150 m ER line positions, which may indicate fresh TCR and capped by weathered or fractured composites. The latter is likely to have altered porosity and be conducive for groundwater storage and movement. The 10-m VD and HD results, together with 20-m HD response (Figures 4.5 & 4.6), showed relatively uniform response, suggesting the presence of either compact silts or fresh bedrock between 7.5-15m depths, whereas 20-m VD, with fluctuating response, may indicate fractured bedrock around 35 m depth. At Bila Rd, Figure 4.7 showed the Tari Formation (TF) to be 20-23 m in depth, whilst this depth gradually increases to around 28-30 towards the river. The increasing depth to bedrock could be attributed to bedrock incision of paleo-SR (section 2.3) upon which the fluvial materials were deposited.

4.13 Possibility of fault/fractured zone

At Dubalevu, the uniform peak in vertical dipole readings (Figure 4.3) in all coil separations between positions 220-280 m may represent the presence of a possible fault/fracture zone between 15-60 m depth. This may induce preferential groundwater flow and hence, increasing EM values. In Tubakeli, Figures 4.10 and 4.11 (below) showed anomalously high horizontal and vertical dipole responses from 40-m coil separation between 240-380 m, in relation to 20-m coil separation response, and thus, suggesting the presence of a fault and/or fractured zone occurring at 30-60 m depth.

Figure 4.10: EM line 1 horizontal dipole at Tubakeli showing high anomalously high readings from 40-m separation suggesting a fractured or sheared zone at around 30 m depth.

Figure 4.11: EM line 1 vertical dipole response at Tubakeli consistently showing anomalously high 40-m separation response and suggesting fractured basement around 60 m.

This interpretation of anomalous EM response (Figures 4.10 and 4.11), together with the fluctuating 20-m VD response (Figure 4.6), suggests fractured conglomerate and rudite unit around 35m depth. Further, the proximity of Tubakeli to the sinistral Nasovatava Fault (NF) (Figures 3.15 & 3.17) suggests the possibility of localized fractured composites, which could be

potential sources of extractable groundwater. At Bila Rd, the anomalously low ER (Figure 4.7) and high EM responses (Figures 4.8 & 4.9) at 0-100 m ER line-positions likely represent a highly fractured Tari Formation, possibly related to the inferred fault splay of the sinistral fault, which is believed to have propagated along Bila Rd (Figures 3.15 and 3.17). The Nasovatava Fault may create an environment conducive for groundwater flow and storage due to the secondary porosity and permeability produced by fracturing.

4.14 Potential drill sites

At Dubalevu, the presence of a possible highly fractured bedrock, as characterized by high vertical dipole responses in all coil separations (Figure 4.3), presents a good opportunity for groundwater exploration and evaluation. Hence, at least two potential groundwater wells will be drilled between 240-280 m EM positions and to a depth range of 20-40 m. At Tubakeli, despite showing stratified ER profiles, the EM responses from Figures 4.6 and 4.11 suggest the occurrence of sheared or fractured basement. Hence, four (4) drill sites have been selected from three adjacent farms to explore the presence of this inferred fractured zone between 30-40 m depths. At Bila Rd, two possible drill sites have been selected at Sugar Ram's farm (Figures 4.7 & 4.9): (1) between 90-100 m ER positions and drilled to 60 m depth to investigate the inferred sheared or fracture zone and (2) between 190-210 m ER positions and drilled to a depth of 35 m to fully penetrate the inferred gravel bar.

In summary, the electrical resistivity and electromagnetic geophysical methods yielded high resolution subsurface models for estimating thickness and extend of overbank and gravelly alluvium deposits, depth to sedimentary bedrock and showing anomalous features denoting possible shear/fracture zones. These subsurface features have guided the selection of drill sites to further explore the physical and chemical conditions of the hydrogeological systems underlying the middle Sigatoka valley.

4.2 Physical Hydrogeology

The groundwater drilling and evaluation stages validated several geophysical survey inferences and proved that groundwater flow patterns are related to lithologic and hydraulic properties of the heterogeneous/complex geological systems (Tihansky, 2005). The following sections will discuss the major hydrogeological groups, namely surficial confining layer system, alluvial aquifer, intermediate confining layer and fractured basement system, before the heterogeneity of the hydraulic properties, structural influences, limited recharge and groundwater flow will be covered.

4.2.1 Hydrogeological framework

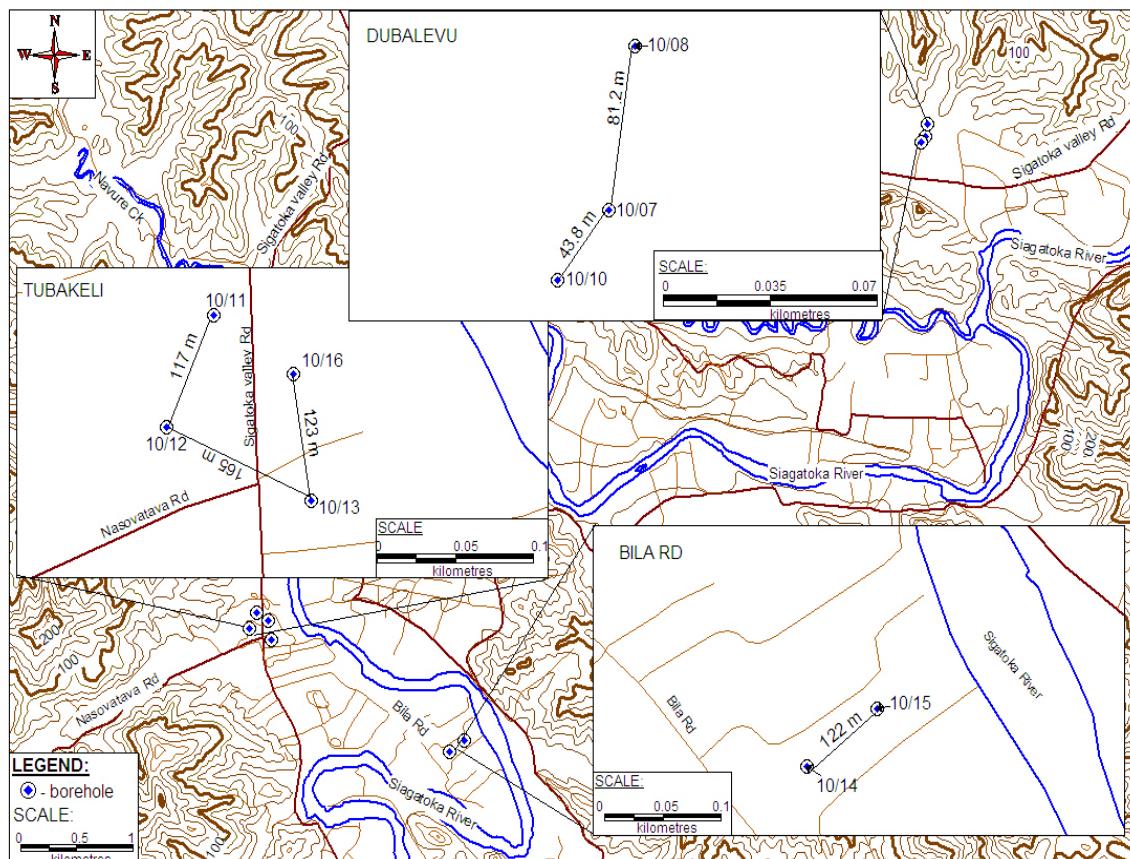

Figure 4.12: Location of boreholes within the study area (details of the wells are provided in Section 3.4.3).

Figure 4.13: hydrostratigraphic log of Dubalevu wells penetrating the surficial confining layer, intermediate confining layer and the fractured composite of the Cici Sandstone.

Figure 4.14: hydrostratigraphic log of Tubakeli wells penetrating the surficial confining layer, intermediate confining layer and the fractured composite of the Takaro Conglomerate/Rudite.

Figure 4.15: hydrostratigraphic log of Bila Rd wells penetrating the surficial confining layer, unconsolidated alluvial system, and the intermediate confining layer and fractured composite of the Tari Formation.

| Site | Hydraulic conductivity (K) (m/s ⁻¹) |
|----------|---|
| Dubalevu | 3.6×10^{-8} |
| Tubakeli | 2.4×10^{-7} |
| Bila Rd | 4.9×10^{-8} |

Table 4.1: measured K using the WF26010 Falling Head permeability cell

Table 4.2: estimated aquifer properties form constant-rate pumping tests.

4.2.11 Surficial confining layer (SCL)

The surficial confining layer is present as flood-overbank deposits and completely weathered colluvium composed of sandy silt and stily loam soil. At Dubalevu, the dark brown, moist-dry, fine grained and non-plastic SCL unit has an average thickness of 10 m and average conductivity (K) value of 7.8×10^{-8} m/s (falling head test estimation - Table 4.1). At Tubakeli and Bila Rd, the brown to light brown sandy silt and silty loam SCL is approximately 11 m thick and recorded the K values of 2.2×10^{-7} and 4.3×10^{-8} m/s, respectively. These low K values suggest infiltration of meteoric and irrigation waters are relatively slow throughout the SCL and vadoze zone.

4.2.12 Alluvial aquifer system (AAS)

The alluvial aquifer system includes unconsolidated sandy gravel deposits penetrated between 11 and 17 m at 10/15 in Bilalevu (Figure 4.17) and the previously drilled Sigatoka Rural Development Project (SVRDP) wells 89/15, 90/15 and 90/16 in Dubalevu with an average depth and aquifer thickness of 40 and 20 m respectively (Davies, 1992). The AAS is composed of sub-angular to sub-rounded, poorly sorted (well graded), medium-coarse gravels (derived from andesite, sandstone, basalt and tonalite) with fine sand. At Dubalevu, the alluvium was estimated at $600 \text{ m}^2/\text{d}^{-1}$ T and $30 \text{ m}/\text{d}^{-1}$ K. At Bila Rd, the 6 m thickness gravel bed penetrated at borehole 10/15 yielded a T of $1644 \text{ m}^2/\text{d}^{-1}$ and a K value of $274.8 \text{ m}/\text{d}^{-1}$ (Table 4.2 & Figure 4.13) The high hydraulic properties are attributed to preferential flows along macro-pores in well graded and unconsolidated sediments and close proximity of the recharge source, the Sigatoka River (Figure 4.12). Further, low observed drawdown suggest that the pump's maximum output is much less than the well's yielding capacity and hence, the test does not prove boreholes safe yield and the effect of pumping on adjacent sources (Twort et.al., 2000).

4.2.13 Intermediate confining system (ICS)

The intermediate confining system refers to the low permeability layer (aquitard) that overlies the fractured basement unit and receives direct (diffuse) recharge from either silt-dominated soil

or alluvial system. In Dubalevu, this unit underlies the SCL and is characterized by the fresh and interbedded bluish grey to grey siltstone and sandstone between 11-23 m (Figure 4.13). At Tubakeli, the unit is composed of fresh siltstone and sandstone matrix supported (dacitic, andesite and tonalite) conglomerate and rudite that was variably penetrated at 13-37 m depths (Figure 4.14). Around Bila Rd, the confining unit is composed of fresh interbedded argillite and bluish grey coarse sandstone at with some andesitic and dacitic clasts, variably penetrated at 6-10 m depths and with the thickness of 31 m (Figure 4.15) The unit is likely to be leaking due to the drawdown observed at 10/15 in response to 10/14 pumping and permitting the calculation of storativity (Table 4.2).

4.2.14 Fractured basement system (FBS)

The fractured basement system at Dubalevu was variably penetrated in wells 10/07, 10/8 and 10/10 between 21 and 34 m depth ranges. The FBS is comprised moderate-highly fractured Cici Sandstone (Figure 4.13). This variable thickness contributed to the variable T, S and K average values of $18.7 \text{ m}^2/\text{d}^{-1}$, 3.15×10^{-4} , $1.86 \text{ m}/\text{d}^{-1}$ for well 10/07 and $3.18 \text{ m}^2/\text{d}^{-1}$, 4.3×10^{-4} , $0.46 \text{ m}/\text{d}^{-1}$ determined for well 10/08 (Table 4.2). At Tubakeli, the FBS is composed of fractured conglomerate and rudite, characterized by moderate fracture development and highly discoloured sandstone matrix locking dacite, andesite and tonalite clasts, with variable thickness between 1 to 6 m thickness. There, this unit exhibits an average transmissivity, storativity and conductivity values of $36.4 \text{ m}^2/\text{d}^{-1}$, 3.4×10^{-4} and $8.1 \text{ m}/\text{d}^{-1}$ at well 10/12 and $16.1 \text{ m}^2/\text{d}^{-1}$, 8.9×10^{-4} and $4.1 \text{ m}/\text{d}^{-1}$ at well 10/13.(Figure 4.14 and Table 4.2). At Bila Rd, the FBS is composed of the weathered Tari Formation penetrated between 45-50 m and showing highly discoloured sandstone with abundant iron oxide coatings with an estimate T, S and K values of $48.7 \text{ m}^2/\text{d}^{-1}$, 1.7×10^{-3} and $9.1 \text{ m}/\text{d}^{-1}$, respectively (Figure 4.15).

4.2.2 Heterogeneity and structural influence

The variable distribution of geological materials, particularly in the alluvial and fractured basement systems, suggests that the groundwater systems are physically heterogenous. The distribution and extent of the sandy gravel in Bilalevu and Dubalevu is limited to the reaches of

historical and present Sigatoka River courses (as detected by the resistivity profiles) with groundwater flow governed by the variable distribution and connectivity of macro-pores, grading of unconsolidated sediments and proximity to recharge source (Kresse & Clark, 2008). This variability is illustrated by the widely ranging hydraulic properties of Dubalevu and Bilalevu unconsolidated alluvial materials, as described above (Section 4.2.12) with the Bilalevu alluvial system shows high yield due to its proximity to the present Sigatoka River (Figure 4.12). Groundwater flow in fractured sedimentary units is constrained by the dimension and distribution of the fractures, aperture and persistence (Cook, 2003). Thus, preferential flow is expected to be concentrated on areas of higher fracture density, aperture and persistence, but the opposite is also true. This is best illustrated by the variable hydraulic properties in the fractured basement under various stress conditions (Table 4.2).

Further, the presence of fractured systems 20-50 m depth in the local sedimentary units signifies the influences of historic tectonic deformation and displacement processes, such as the ENE-WSW trending Nasovatava Fault and its associate shears or fault splays, in controlling the development of fractures and joint systems (secondary porosity) in the sedimentary basement. These, together with precipitation overtime, cause selective dissolution of carbonate minerals causing fracture expansion and enhancing preferential flow (Fetter, 2001) and hence, create an environment conducive for appreciable groundwater storage and flow.

4.2.3 Limited recharge

All but one tested borehole showed limited groundwater recharge defined as continued drawdown during constant rate pumping. Pumping of wells 10/07 and 10/08 at Dubalevu showed continued drawdown of the FBS during the test period in response to the differential pumping rates of 10.6 and 0.57 L/s, respectively. The varying aquifer responses (Table 4.2) could be attributed to the variable thickness, density and dimensions of the FBS, as well as limited recharge (Figure 3.39). At Tubakeli, the pumping of boreholes 10/13 and 10/12 at 0.9 and 5 L/s, respectively, recorded continued drawdown indicative of limited recharge. Borehole 10/12 generated significantly different storativity values of 6.7×10^{-4} during drawdown and 8.6×10^{-6} during recovery. This variability suggests the aquifer was stressed beyond its potential and

hence, shows limited recharge as governed by the variability of thickness, density and dimensions of the FBS (Figure 3.40). At Bila Rd, borehole 10/14, recording a higher storage coefficient of 1.7×10^{-3} , which may suggest either a highly sheared zone with altered porosity and enhanced storage capacity or a proximal recharge source (through vertical down leakage) from the overlying ICS as drawdown was observed at borehole 10/15 with SR being the source. Again, the continued drawdown, although minimal, observed at borehole 10/15 indicated the growth of a cone of depression and thus, limited recharge. However, 10/15 showed little drawdown response to the 1.85 L/s long-term pumping and no drawdown observed at 10/14. This suggests well 10/15 was receiving abundant recharge from an adjacent source, in this case the Sigatoka River, and hence, the cone of depression did extend towards well 10/14 (Figure 4.12).

4.2.4 Groundwater flow direction from periodical monitoring

Figures 4.16 and 4.17 showed the average potentiometric surface that is oriented towards the Sigatoka River and suggests that river flow is composed of groundwater discharge.

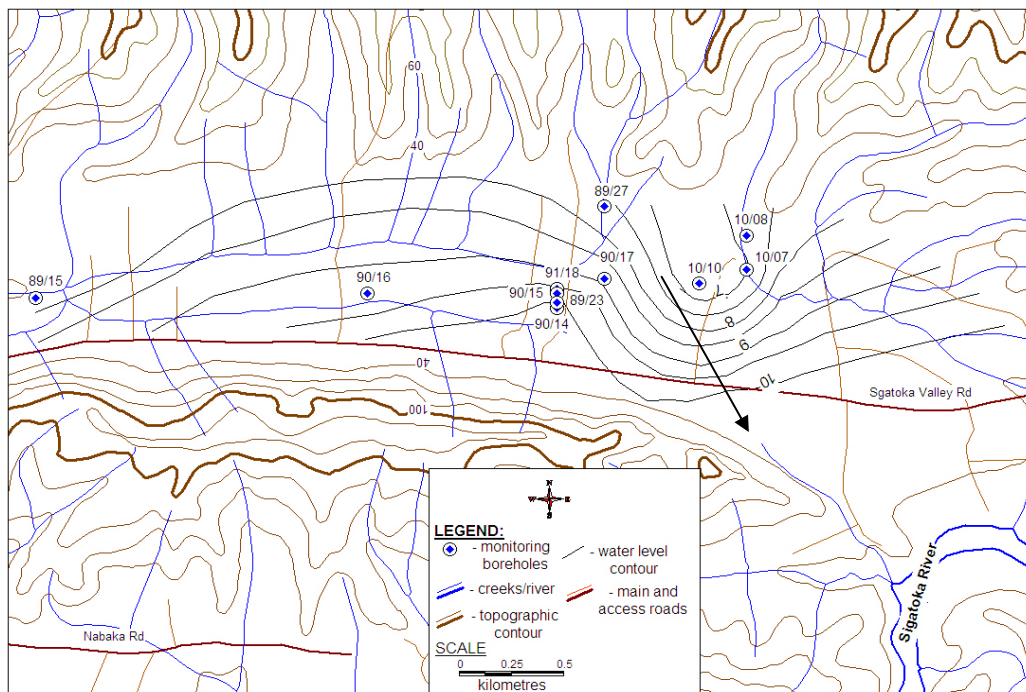

Figure 4.16: Dubalevu water level contour derived from the average of the two measurement periods and showing a NW-SE flow direction to the Sigatoka River.

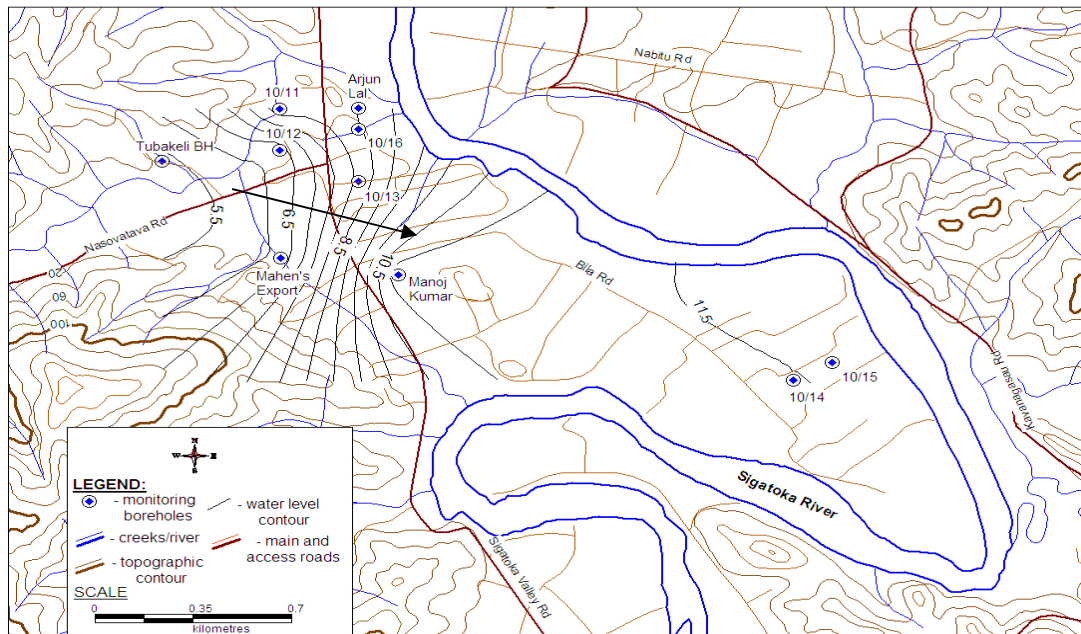

Figure 4.17: Bilalevu water level contour, taken from the averages of the two monitoring periods, showing WNW-ESE flow direction towards the Sigatoka River.

Groundwater in Dubalevu flows in a NW→SE direction whilst a WSW→ESW flow direction was recorded in Bilalevu. This flow pattern is a function of recharge conditions and the spatial variation of hydraulic properties of the aquifer system (Tihansky, 2005). However, the overall decline in water levels in most of the monitored wells (Tables 3.7 and 3.8), suggests that the groundwater system, comprising alluvial and fractured systems, is responding moderately to climatic variations, such as the reduced recharge induced by the dry condition (August and October). These findings suggest that the underlying hydrogeological system is dominated by a shallow aquifer system that receives rainfall-recharge through either fracture-induced preferential flows or unconsolidated macro-pores in the alluvium.

In summary, the physical hydrogeological framework is capped by surficial alluvium systems of silt-dominated confining unit and an unconsolidated sandy gravels aquifer, and underlain by intermediate confining and fractures systems of the local sedimentary units. Variable aquifer parameters estimates, from the pumping tests, are owed to the differing distribution and connectivity of macro-pores and preferential flow paths, heterogeneity of groundwater systems and variable recharge, whilst regional groundwater flow pattern in the valley appear to be oriented towards the Sigatoka River.

4.3 Hydrochemistry

This section first interprets the hydrochemistry of the study area using chemical and isotopic principles. Second, this section considers the observed variability of the chemical and isotopic results in relation to the heterogeneity and complexity of local hydrogeological system and hydrological cycle.

4.31 Hydrochemical classification:

Aqueous geochemical compositions (Tables 3.11-3.13 and Figures 4.18 and 4.20) indicate that the Middle Sigatoka Valley (MSV) waters include two major facies, namely $\text{Ca}(\text{HCO}_3)_2$ and $\text{Na}^+(\text{HCO}_3)$ type waters. The latter was observed in deep groundwater sources, drilled to 47-60m, while the former was observed in shallow sources penetrated at 20-45 m. The dominant $\text{Ca}(\text{HCO}_3)_2$ type water can be attributed to rainfall-derived sources, with enrichments in organic carbon due to soil respiration (Wallick, 1981) ultimately causing dissolution of carbonate minerals present in the local sedimentary units (Figure 4.20), most of which are derived from Qalimare Limestone during the Late Miocene (Hathway, 1995). Figure 4.18, below, showed the dominance of $\text{Ca}(\text{HCO}_3)_2$ type waters whilst a number of samples occupy the 'no-dominant cations' boundary suggesting mixed sources from halite (NaCl) and dolomite (CaMgCO_3) weathering. The $\text{Ca}(\text{HCO}_3)_2$ type water sources, therefore, suggest rapid and shallow flow systems dispersing through either alluvial or fractured systems (including springs) with moderate-high transmissivity and conductivity (Table 3.6).

However, two sites, namely B5 and B18 (Table 3.13 and Figures 4.18 & 4.20), showed $\text{Na}(\text{HCO}_3)$ type waters, which suggest a deeper groundwater source, consisting of sodium enriched connate groundwater, and more limited recharge rates. Well B5, drilled to 47 m depth, showed the depletion of calcium and magnesium in relation to most $\text{Ca}(\text{HCO}_3)_2$ type sources and the enrichment of Na^+ . These data suggest the precipitation of dolomite as a secondary mineral and the associated ionic exchange of Ca^{2+} and Na^+ as shown by an anomalously high Na^+ concentration of 156 mg/L in relation to $\text{Ca}(\text{HCO}_3)_2$ (Hiscock, 2005).

Figure 4.18: piper plots of all sampled water sources in the study area.

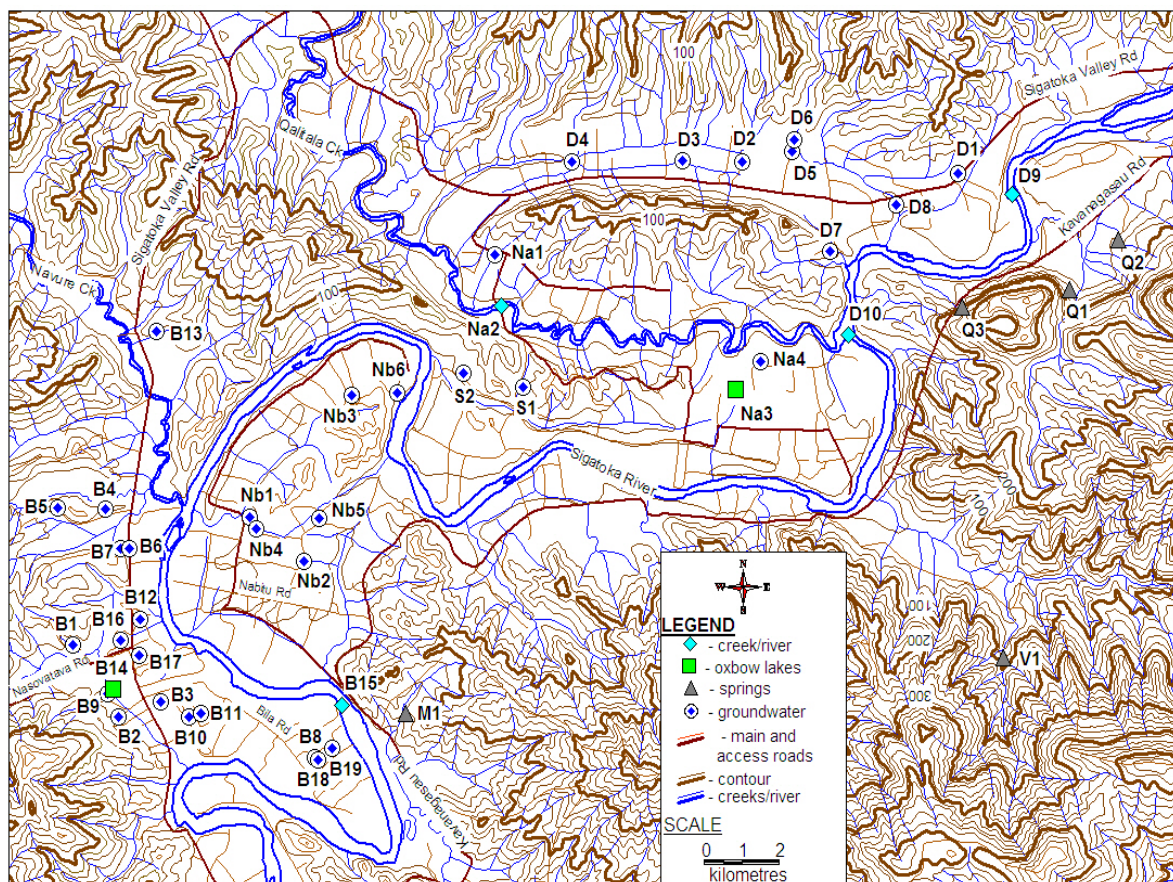

Figure 4.19: Location of map of chemical sampling sites with unique site ID.

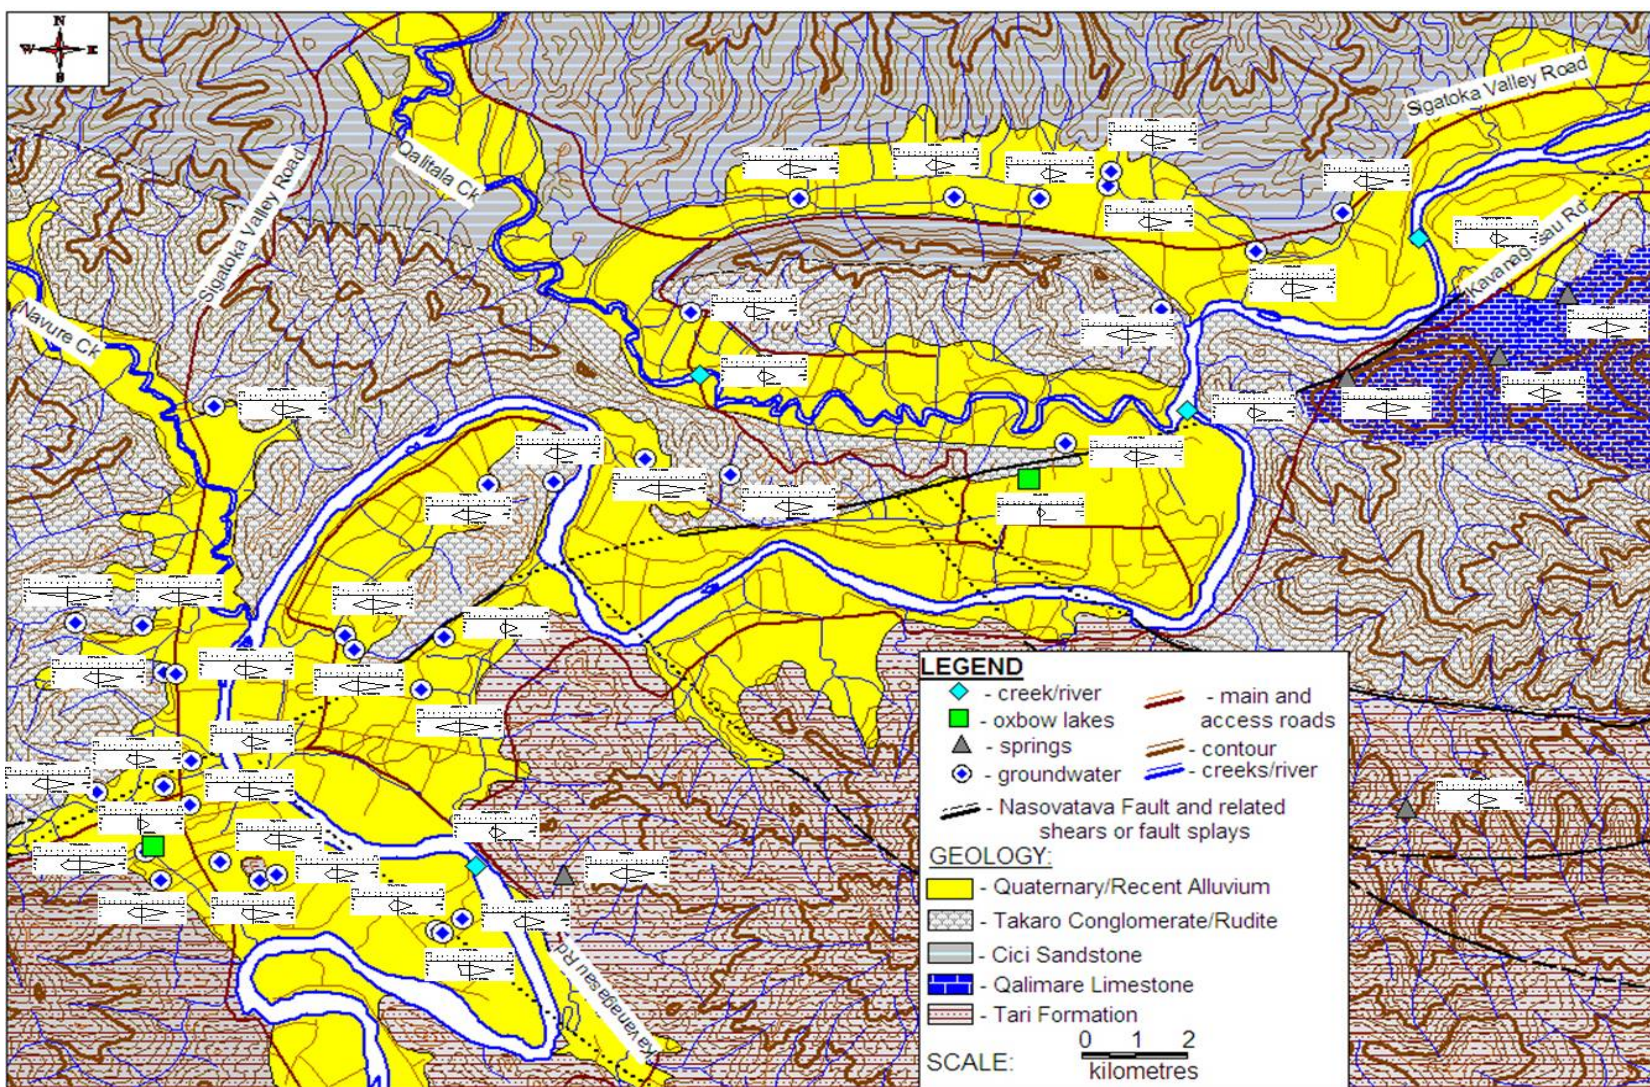

Figure 4.20: stiff plots of all collected samples superimposed on geological units and showing the dominance of $\text{Ca}(\text{HCO}_3)_2$ type water with two sites (B5 and B18 recording $\text{Na}(\text{HCO}_3)$ type groundwater across the Middle Sigatoka Valley.

The sample from bore B18, 60 m depth, showed a slightly higher $[\text{Na}^+]$ as opposed to Ca^{2+} (relative to well B5) and in relation to well B19 suggests mixing between shallow and deep sources. The elevated Na^+ can be attributed to upward flow of connate groundwater or dissolution of evaporates, such as halite, that is mixing with $[\text{Ca}^{2+}]$ of shallower source. The drawdown response of site B19 (located near the river) in relation B18 pumping (Figure 3.38 & Table 3.6) confirms mixing from a shallow $[\text{Ca}^{2+}]$ source, likely from either the adjacent alluvial system or the Sigatoka River.

In summary, the chemical dataset suggest two flow systems exist in the middle Sigatoka Valley:

- (1) shallow system of $\text{Ca}(\text{HCO}_3)_2$ type water dominated by rapid carbonate weathering and adequate meteoric recharge; and
- (2) deeper system of $\text{Na}^+(\text{HCO}_3)$ type water dominated by connate groundwater with some mixing.

4.32 Isotopic composition – source of water resources

The stable isotopic composition of study area waters (Table 3.14), range between -5.71 to 0.08 ‰ $\delta^{18}\text{O}$ and -35.95 to 2.35 ‰ δD for groundwater, -5.96 to -0.16 ‰ $\delta^{18}\text{O}$ and -36.57 to -18.98 ‰ δD for springs, -5.17 to -0.47 ‰ $\delta^{18}\text{O}$ and -32.88 to -5.89 ‰ δD for creek/rivers sources, 0.38 to 0.63 ‰ $\delta^{18}\text{O}$ and -18.84 to -10.55 ‰ δD for oxbow lakes, and -4.58 to 1.19 ‰ $\delta^{18}\text{O}$ and -28.89 to 8.76 ‰ δD for rainwater. Figure 4.1 below, a plot of δD vs $\delta^{18}\text{O}$, reveals the relatively negative compositions, with variable enrichments of deuterium and ^{18}O , on a positively linear trend. This further shows that the groundwaters exhibit similar isotopic compositions to surface sources, most of which plot along a local meteoric water line (LMWL) of slope 4.3. This demonstrates a meteoric origin for groundwaters in the area. Meteoric waters are either flowing into and through the surface systems or dispersing at both variable depths and flow rates through alluvial and fractured systems (Table 4.2) with variable influences of evaporation in vadoze zone and surface environment prior to infiltration. The most negative isotopic values, plot close to the global meteoric water line (GMWL), represent rapidly flowing and/or dispersing meteoric recharge with negligible evaporative influences, whilst the more positive isotopic compositions suggest moderate-intense modification via free evaporation and/or mixing with older residual evaporated water in either surface storage, groundwater storage or infiltrating the vadoze zone.

Figure 4.21: plot of $\delta^{18}\text{O}$ (‰) vs δD (‰) of sampled water sources in the study area.

This linear trend suggests that water, from headwaters (i.e. recharge zone), evolves from a relatively homogeneous meteoric source (i.e. local recharge plotted close to GMWL) to a mixture of connate groundwater and slightly enriched ^{18}O evaporated surface water infiltrating the vadoze zone (Walker & Krabbenhoft, 1998). This enrichment and mixing of groundwater is well illustrated by the enriched deuterium and more positive ^{18}O recorded in sample B11 (0.08 ‰ $\delta^{18}\text{O}$ and -15.62 ‰ δD , Table 3.14, Figures 3.67-3.68), which is possibly sourced from the mixing of evaporated connate groundwater and evaporated rainfall flushing through the fractured basement, as well as evaporated surface water infiltrating the vadoze zone.

Figure 4.22: plot of $\delta^{18}\text{O}$ vs chloride (mg/L) dominated by isotopic depletion and low Cl^- (0-20 mg/L).

However, the low chloride concentration in all the sampled water sources as shown by Figure 4.22, (1.02-34.76 mg/L, Table 3.15) in relation to most of the costal and geothermal springs in Viti Levu and Vanua Levu sampled in 1980 (50-200 mg/L, Cox & Hulston, 1980), suggest that elevated chloride in valley waters via evaporation during the dry season is likely to dampened by abundant rainfall recharge-induced dilution in the wet season, hence, suggesting abundant meteoric recharge seasonally. These, together with the low temperature measured in all water sources (25.5-30.7 °C, Table 3.9) in relation to the 1980 thermal spring sources (Figure 3.70), eliminate the possibility of magmatic mixing within the study area.

Figure 4.23: $\delta^{18}\text{O}$ (‰) vs δD (‰) plot of groundwater and springs in the study area together with groundwater and springs data documented in Cox and Hulston (1980).

Figures 4.23 and 4.24 showed the similarities and differences of the study area and Viti Levu sampled sources in the previous study conducted in 1980 (Cox & Hulston, 1980). Both the datasets exhibited LMWL of slopes < 8 , which can attributed to the condensation and precipitation of vapor generated from rapid evaporation prevalent in tropical islands zone (Sharp, 2007). The plotting of more negative isotopic close to the GML and the linear trend of more positive isotopic compositions are common in both datasets.

Figure 4.24: $\delta^{18}\text{O}$ (‰) vs δD (‰) plot of surface sources, namely creeks, rivers, oxbow lakes and rain for this research, and surface sources sampled in 1980.

These suggest meteoric-derived waters that are variably modified by either evaporation or mixing with other residual evaporated waters. However, the major difference is observed by the slopes of residual evaporation lines in both datasets. The 1980 data showed a LMWL slope of ~ 6 , whilst the study area exhibited a relatively lower LMWL slope. The fact the LMWL of the study area has a slope < 4.3 suggests the influence of arid climate in the leeward area that drives the kinetic fractionation and that mixing of residual evaporated waters results in the enrichment of deuterium and ^{18}O in the liquid phase (Cox & Hulston, 1980). This enrichment is exemplified by the more positive isotopic composition recorded in both the oxbow lakes (0.4‰ and 0.6‰ $\delta^{18}\text{O}$, Table 3.14 & Figure 3.67-3.68), which can attributed to the evaporation-induced diffusional processes prevalent in lakes at low humidity (Pentecost, 2005).

4.33 Complexity of surface and groundwater systems

The heterogeneity and/or complexity of surface and groundwater flow systems and processes are illustrated by the (1) high variability in chloride concentration, (2) variable enrichment/depletion of sulfate, magnesium locally, (3) variable pH values and HCO_3^- , (4) variable isotopic compositions in surface flows, and (5) signatures of groundwater and surface interaction. The following section further explores these interesting geochemical patterns.

4.33.1 variability of chloride concentration (Cl^-)

Subsurface $[\text{Cl}^-]$ sources may include saline intrusion, ionically enriched connate groundwater and evaporates weathering such as halite (Tihansky, 2005). Table 3.15 and Figure 4.22 showed that the water sources in the MSV are dominated by low $[\text{Cl}^-]$ (1-18 mg/L): this may indicate abundant meteoric recharge-induced dilution. Numerous sites, namely S2, B9 and B3, showed slightly elevated $[\text{Cl}^-]$ (>30 mg/L, Table 3.15), which suggests proximity to some $[\text{Cl}^-]$ sources.

| Location | Natadola Harbour | Natadola Harbour |
|--------------------------------|------------------|------------------|
| Region | SW Viti Levu | SW Viti Levu |
| Season | Wet | Dry |
| pH | 5.46 | 5.24 |
| HCO_3^- (mg/L) | 0.94 | 1.23 |
| Ca^{2+} (mg/L) | 0.17 | 0.09 |
| Cl^- (mg/L) | 1.22 | 1.8 |
| EC ($\mu\text{S}/\text{cm}$) | 6.9 | 9.6 |
| Fe^{2+} (mg/L) | 0.04 | 0.03 |
| Mg^{2+} (mg/L) | 0.07 | 0.07 |
| Mn^{2+} (mg/L) | 0.02 | 0.028 |
| K^+ (mg/L) | 0.11 | 0.193 |
| Si (mg/L) | 0.07 | 0.06 |
| Na^+ (mg/L) | 0.6 | 0.938 |
| SO_4^{2-} (mg/L) | 0.7 | 0.77 |

Table 4.3: bulk chemistry precipitation measured at Natadola Harbour, southwest Viti Levu showing mean chloride concentration of 1.5 mg/L (Waterloo et.al., 1997).

| Type | Location | SampleID | Collection Date | $\delta\text{D}(\text{‰})$ | $\delta^{18}\text{O}(\text{‰})$ | Cl^- (mg/L) |
|-----------|----------|----------|-----------------|----------------------------|---------------------------------|----------------------|
| Rainwater | Suva | R1 | 13/07/10 | 8.64 | 0.16 | 5.11 |
| Rainwater | Bilalevu | R2 | 31/08/10 | -28.90 | -4.58 | 1.06 |
| Rainwater | Bilaevu | R3 | 25/11/10 | 8.76 | 1.20 | 5.84 |

Table 4.4: rainwater samples data extracted from Table 3.15

Variability in chloride was also recorded in two rain samples collected at Bilalevu (Rn2 and Rn3 - Table 4.4). Sample Rn2 (1.1 mg/L), the dry period rainfall sample, recorded similar $[\text{Cl}^-]$ to

rainwater measured at Natadola Harbour rainfall station, southwest Viti Levu, with 1.5 mg/L (Waterloo et.al., 1997) (Table 4.3). This suggests similarity in sources of air masses and atmospheric conditions. Due to low humidity and intense evaporation common in dry period (Sharp, 2007), precipitation may have occurred at higher altitude and will be less enriched in D and ^{18}O due to Rayleigh fractionation. This is supported by negative δD and $\delta^{18}\text{O}$ values of -28.9 ‰ and -4.58 ‰, respectively, in relation to Rn1, Rn3 and 1980 rain samples (Table 4.4 and Figure 4.21 & 4.23). Sample R3 (5.8 mg/L Cl^-), collected in November, showed similar $[\text{Cl}^-]$ to rainwater collected in the windward area, near Suva, in July, 2010 (5.1 mg/L; Table 4.4). This suggests similar sources of saturated air masses and similar atmospheric conditions (e.g. relatively high humidity) at low altitudes during the wet season. Hence, wet season rainfall will likely to experience variable amounts of Rayleigh fractionation depending on storm-track path and water recharge processes in the air parcel (Sharp, 2007). This interpretation is supported by more positive δD and $\delta^{18}\text{O}$ values of +8.76 ‰ and +1.2 ‰, respectively, in relation to R2 and some of the 1980 rain samples (Table 4.4 & Figures 4.21 & 4.23). In summary, the isotopic composition of rain is variable owing to the combined effects of Rayleigh fractionation dominant during the wet season and the seasonal amount effect known to occur in tropical regions.

4.33.2 variability in sulfate, sodium and magnesium

Elevated $[\text{SO}_4^{2-}]$ in numerous samples, namely D9, D10, B3 and B9, suggests gypsum dissolution is occurring along numerous flow paths in the study area (Tables 3.12 and 3.13). The fact that numerous groundwater sources plot in the ‘no-dominant cations’ boundary (Figure 4.19), suggests mixing between end-member sources is a dominant control on groundwater chemistry. Gypsum, halite (NaCl) and dolomite ($\text{Ca}^{2+}\text{Mg}^{2+}$) dissolution at depth contributes to the complexity and heterogeneity of groundwater flow systems.

4.33.3 variability of pH values and HCO_3^-

The measured groundwater pH range of 6-8 (Table 3.9), in relation to rainfall pH of 5.3 measured at the southwest of Viti Levu (Waterloo et.al., 1997; Table 4.3), represents the varying evolution of meteoric-derived groundwater from acidic to neutral to mildly alkaline state. This evolution can be

attributed to variability in recharge, variable ionic exchange processes and variable concentration of aqueous CO₂.

Figure 4.25: pH vs [Cl⁻] (mg/L) plot of sampled water sources in the study area showing highly scattered data.

Figure 4.26: pH vs [HCO₃⁻] (mg/L) plot of sampled water sources in the study area showing highly scattered data.

Figure 4.27: $\delta^{18}\text{O}$ (‰) vs $[\text{HCO}_3^-]$ (mg/L) plot of sampled water sources in the study area showing highly scattered relationship.

Figures 4.25 and 4.26 show a highly complex relationship between pH vs $[\text{HCO}_3^-]$ and pH vs $[\text{Cl}^-]$, further reinforcing the variable recharge, and physical and chemical processes at work in the system. The sampled springs, most of which are water table springs (section 3.1.3.2), are mildly alkaline waters (7.1-8.1, Table 3.9) attributable to rapid calcite dissolution and bicarbonate enrichment derived from the Qalimare Limestone (Figure 4.20). Figure 4.27 shows a similar, highly scattered, relationship between $\delta^{18}\text{O}$ and $[\text{HCO}_3^-]$ suggesting variable amount of evaporation on water sources in the study area and varying HCO_3 enrichment. Again, these findings, reinforce the complexity of the groundwater and surface water processes that influence the local hydrogeochemistry.

4.33.4 signatures of groundwater-surface interaction

A number of groundwater samples provided evidences of groundwater-surface interaction. Sample D2 and D3 (drilled into sandy gravel to 40-45 m depths at Dubalevu) and sample B19 (drilled into silty sand in Bilalevu) and showed low EC, HCO_3 and TDS similar to creeks and river samples D9, D10 and B15 (Tables 4.5, 3.12 and 3.13).

| SampleID | Location | Type | EC | TDS | HCO ₃ ⁻ (mg/L) | δD(‰) | δ ¹⁸ O (‰) | Cl ⁻ (mg/L) |
|----------|----------|------|-------|-------|--------------------------------------|--------|-----------------------|------------------------|
| D2 | Dubalevu | GW | 289.3 | 188 | 186.7 | -24.16 | -3.20 | 2.9 |
| D3 | Dubalevu | GW | 317.8 | 203.8 | 209.1 | -22.57 | -2.68 | 3.1 |
| D9 | Dubalevu | R | 249 | 154 | 134.3 | -32.88 | -5.17 | 8.5 |
| D10 | Dubalevu | R | 252 | 156 | 140.3 | -28.62 | -4.32 | 7.1 |
| B15 | Bialevu | R | 213.6 | 132.2 | 115.9 | -22.38 | -2.46 | 3.9 |
| B19 | Bilalevu | GW | 390 | 241.7 | 235.5 | -35.66 | -5.60 | 4.3 |
| Nb5 | Nabitu | GW | 220.8 | 136.5 | 127 | -22.84 | -2.93 | 4.2 |

Table 4.5: groundwater (GW) and river (R) samples showing signatures of groundwater-surface water interaction.

With a low Cl⁻ of 2.9 and 3.1 mg/L and isotopic composition of and -3.2 and -2.7‰ δ¹⁸O, it is likely that these alluvial sources receive direct recharge from leakage of surface water bodies, demonstrating the connectivity of surface and groundwater systems as was earlier shown by the geophysics results. Further, well Nb5, drilled to 40m into local conglomerate and rudite unit (Table 4.5 and Figures 4.19 and 4.20) also recorded EC and TDS similar to surface samples D9 and D10, together with depleted isotopic composition of -2.9‰ δ¹⁸O in relation to surrounding wells in Nabitu (sites Nb1, Nb2 and Nb4 on Figures 3.67 and 3.68), represents either leakage and mixing through the conglomerate unit or direct recharge from the SR possibly through preferential flow through fractured systems, and hence, reinforcing the complexity in flow conditions.

In summary, aqueous geochemistry of the Middle Sigatoka Valley is composed of:

- Ca(HCO₃) type waters of shallow flow systems receiving abundant meteoric recharge with few deep flow systems showing Na(HCO₃) type waters and limited recharge;
- Meteoric derived waters, defined by a linear trend of stable δD and δ¹⁸O isotopes along a LMWL of slope 4.3, that is either flowing into and through the surface systems or dispersing at both variable depths and flow rates through alluvial and fractured systems with variable influences of evaporation in vadoze zone and surface environment prior to infiltration; and
- Highly complex interactions between seasonally variable hydrological conditions, surface water bodies and heterogeneous geological systems as demonstrated by the highly variable chloride concentration, rainfall chloride and isotopic compositions, pH values, HCO₃ enrichments and elevated end-member sources along numerous groundwater flow paths.

4.4 Groundwater recharge estimation

Physical water balance (PWB) and chemical mass balance (CMB) estimates for the middle Sigatoka Valley system yield recharge estimates that differ by ~ 300 %. These differing results stem from the highly complex and temporally dynamic physical and chemical processes at work in the system. The following section presents these two models in relation to groundwater recharge in the Middle Sigatoka Valley.

4.41 Physical water balance

| Parameters | Wet season | Dry season |
|---|------------|------------|
| Land area (m ²) | 40000000 | 40000000 |
| Precipitation (m/month) | 0.223 | 0.089 |
| Evapotranspiration (m/month) | 0.138 | 0.098 |
| Total Precipitation (m ³ /month) | 8920000 | 3560000 |
| Total Evapotranspiration (m ³ /month) | 5520000 | 3920000 |
| Total runoff (m ³ /month) (assumed 4.1 % of P) | 365720 | 145960 |
| Total number of Groundwater sources | 26 | 29 |
| Average pumping rate (L/s) | 1.06 | 1.19 |
| Average daily abstraction duration (hrs) | 5.15 | 4.93 |
| Daily groundwater abstraction (m ³ /day) | 510.96 | 612.48 |
| Total groundwater abstraction (m ³ /month) | 15328.87 | 18374.50 |
| Total number of low lift pump | - | 14 |
| average pumping rate (L/s) | - | 9 |
| average pumping duration (hrs) | - | 6 |
| Daily low-lift pump abstraction (m ³ /day) | - | 2721.6 |
| Low-lift pump abstraction (m ³ /month) | - | 81648 |
| Total number of groundwater irrigation source | - | 3 |
| average pumping rate (L/s) | - | 2.3 |
| average abstraction duration (hrs) | - | 3 |
| Daily groundwater abstraction | - | 74.52 |
| Groundwater irrigation (m ³ /month) | - | 2235.6 |
| Total irrigation (m ³ /month) | - | 83883.6 |
| Total Recharge (m ³ /month) | 3018951.13 | -440450.90 |
| Total Recharge (m/month) | 0.08 | -0.01 |

Table 4.6: groundwater recharge estimation via physical water model.

Table 4.6 showed groundwater recharge rate of 0.08 m/month in the wet season whereas a -0.01 m/month was estimated for the dry season. Despite the limitation of the assumptions and the limited data available, the slightly higher precipitation in relation to evapotranspiration in the wet season contributed to a surplus in groundwater recharge and would result in an increase in groundwater levels and storage (Kumar, 1996). This rainfall recharge is likely to occur mainly in the fractured

sedimentary units, from which most of the drinking wells are sourced, through rapid dispersion along preferential flow paths. Conversely, the recharge deficit in the dry season is largely controlled by excess evapotranspiration in relation to precipitation. Therefore, groundwater abstraction for both drinking and irrigation during the dry season are likely to utilize non-renewable (in the dry period) groundwater storage (Water and Rivers Commission, 2002). These activities, if not properly regulated, could have adverse ecological and hydrological impacts to groundwater systems ultimately reducing streams and springs discharge. Such a result could jeopardize the availability and usability of groundwater resources in the long-term.

4.42 Chloride mass balance

| Season | Wet | Dry |
|--------------------------------|------------|------------|
| Precipitation (m/month) | 0.223 | 0.89 |
| Chloride (mg/L) | | |
| Rain | 5.84 | 1.06 |
| B8 | 6.65 | 9.75 |
| D4 | 2.22 | 5.98 |
| D3 | 3.99 | 4.43 |
| Recharge (m/month) | | |
| B8 | 0.19 | 0.10 |
| D4 | 0.58 | 0.16 |
| D3 | 0.33 | 0.21 |

Table 4.7: groundwater recharge estimation using chemical mass balance model.

Table 4.7 showed an estimated recharge rate 0.2 to 0.6 m/month in the wet season. The variability in recharge rate in the selected alluvial aquifers is attributed the differences in material compositions. Well B8, drilled to 20 m depth into a silty sand aquifer in Bilalevu, recorded a lower recharge estimate possibly due to the abundance in fine materials. In contrast, wells D3 and D4, penetrated into sandy gravels, recorded a higher recharge estimate due to macro-pores and well graded sediments. The high recharge rate during the wet season suggests abundant recharge from the adjacent surface networks, including surface runoffs, interflow, throughflows and baseflow (Brassington, 2007 and Green, 1986), during the period of high flow. Hence, the alluvial aquifers recorded low $[Cl^-]$ due to recharge-induced dilution (Kresse & Clarke, 2008). The dry season, an

anticipated recharge deficit due to low precipitation rate and high evapotranspiration, showed continued recharge of 0.1-0.2 m/m⁻¹, with impacts of high evaporation and water table decline shown by slight increases in [Cl⁻], Table 3.8.5. The low but sustained recharge rate may indicate a period of diminished flow from surface sources, consisting only of base flow (Brassington, 2007 and Green, 1986). These model results suggest that the hydraulic connection of alluvial aquifers to surface water bodies results in continued but seasonally variable recharge governed primarily by climatic variations.

In summary, the middle Sigatoka Valley groundwater system is recharged through meteoric recharge that is dispersing rapidly through the fractured flow paths and seasonally variable leakage, from surface water bodies, dispersing through macro-pores of alluvium deposits. The negative and low recharge rate in the dry period, together with the excess groundwater abstraction, is a serious concern due to the utilization on non-renewable groundwater storage and could have serious implications of the sustainability of groundwater in the long-term.

4.5 Conclusion & Synthesis

- The interpretation of geophysical data permitted the estimation of alluvium materials (including silt-dominated deposits and sand-gravels possibly marking buried river channels), depth to bedrock and possible shear/fracture zones at Dubalevu, Tubakeli and Bila Rd culminating in the selection of potential groundwater drill sites
- The physical hydrogeological framework is composed of
 - surficial silt-dominated layer of with conductivity (K) values of 7.8×10^{-8} m/s at Dubalevu, 2.2×10^{-7} m/s at Tubakeli and 4.3×10^{-8} m/s at Bila Rd.
 - alluvial system, of unconsolidated sandy-gravel, have an estimated transmissivity (T) and K values of 600 m²/d⁻¹ and 30 m/d⁻¹ at Dubalevu and 1644 m²/d⁻¹ and 274.8 m/d for well 10/15 in Bilalevu
 - intermediate confining units of unweathered/unfractured sedimentary units
 - fractured sedimentary units of variable T, storativity (S) and K 10.9 m²/d⁻¹, 3.7×10^{-4} , 1.16 m/d⁻¹ for the fractured sandstone at Dubalevu, 26.2 m²/d⁻¹, 6.1×10^{-4} , 6.1 m/d⁻¹ for the fractured conglomerate/rudite at Tubakeli and 48.7 m²/d⁻¹, 1.7×10^{-3} , 9.1 m/d⁻¹

for the fractured sandstone and argillite at Bila Rd as estimated during the long-term pumping at various stress conditions.

- the variable aquifer responses suggest the heterogeneity and complexity of groundwater systems and limited recharge.
- Regional groundwater is flowing towards the Sigatoka River (NW→SE and WNW→ESE in Dubalevu and Bilalevu, respectively), whilst the sensitivity of groundwater level to the climatic conditions suggest a shallow aquifer system underlying the Dubalevu and Bilalevu areas.
- Aqueous geochemistry showed that the study area include:
 - dominant $\text{Ca}(\text{HCO}_3)_2$ type waters of shallow flow systems receiving abundant meteoric recharge with few deep flow systems showing $\text{Na}(\text{HCO}_3)$ type waters and limited recharge;
 - Meteoric derived waters, defined by a linear trend of stable δD and $\delta^{18}\text{O}$ isotopes along a LMWL of slope 4.3, that is either flowing into and through the surfaces systems or dispersing at both variable depths and flow rates through alluvial and fractured systems with variable influences of evaporation in vadoze zone and surface environment prior to infiltration; and
 - Highly complex interactions between seasonally variable hydrological conditions, surface water bodies and heterogeneous geological systems as demonstrated by the highly variable chloride concentration, rainfall chloride and isotopic compositions, pH values, HCO_3 enrichments and elevated end-member sources along numerous groundwater flow paths.
- Groundwater recharge in the Middle Sigatoka Valley, through physical and chemical mass models, was estimated to be 0.08 to 0.6 m/month and -0.1 to 0.2 m/month during the wet and dry seasons, respectively. Groundwater recharge occurs through either rapid dispersion of rainfall along fractured flow paths or seasonally variable leakage from surface water bodies into alluvium macro-pores.
- In summary, groundwater resources in the study area is highly limited in recharge (due to climatic control) with highly variable and uncertain storage capacity (due to heterogeneity

and complexity of geological systems) and hence, reliable investigation procedures and technologies, together with proper protection/management strategies, will be required to ensure the reliable and accurate modeling of hydrogeological system and as well as to safeguard the availability and usability of groundwater in the long-term.

Chapter 5: Groundwater issues & sustainable management

5.0 Introduction

The following sections present the major challenges and/or issues encountered during and after this research before outlining a number of recommendations relative to the protection and sustainable management of groundwater.

5.1 Groundwater Issues/Challenges

During the course of this investigation, numerous groundwater management issues, including the (1) large uncertainties and associated costs of hydrogeological investigation, (2) unregulated groundwater abstraction and drilling, (3) equitable allocation mechanisms, (4) absence of groundwater legislations and (5) climate change, were observed in the study area. These will be discussed in the next section such that these critical aspects are intertwined with respect to the groundwater sustainability.

5.1. Groundwater Issues

5.1.1 Large uncertainties and high associated costs of hydrogeological investigation

This research demonstrates the large uncertainties of hydrogeological systems, as well as the massive associated financial cost involved. For example, a borehole, costing around \$5,000-10, 000 depending on depth (Mr Jonati Railala, Mineral Resources Department, pers.comm, 2010), may only intercept a small volume of a water bearing unit. In fractured systems, the borehole is likely to intersect no fissures or bedding planes large enough to render usable water supply and vice versa (Twort et.al., 2000), as shown by the highly variable yield of boreholes located in close proximity (Figure 3.4.1 and Table 3.4.2). Secondly, geophysical surveys, a costly and time consuming exercise, require adequate site-specific surface geological knowledge, including records of existing boreholes, to generate high resolution subsurface models. These models usually entail large uncertainties that often require groundwater exploration drilling for data validation purpose, which, again, will be an added cost and hence, augments the high uncertainties and associated costs as

governed by the heterogeneity and complexity of hydrogeological conditions (section 4.2.2 and 4.3.3).

5.1.2 Unregulated groundwater drilling and abstraction

The rapid growth in the number of privately drilled wells (PDW) within the study area, most of which are penetrating the fractured basement systems (FBS), represents major the human impact on groundwater systems. Despite the heterogeneity and limited recharge in the fractured basement system (section 4.2.3), Table 3.16 showed variable groundwater abstraction, with a volume of 510-612 m³/month. This unregulated abstraction rate is likely to exert pressure on the aquifer storage in the fractured (local) sedimentary units (from which most of these wells are sourced) in the dry season. This could lead to deterioration in groundwater quality and quantity, as well as adverse ecological and hydrological impacts on groundwater-dependant ecosystems and streams and springs discharges. To date, the excess groundwater abstraction is strongly related to unregulated drilling by private drilling companies (PDC), which is now prevalent around Fiji. As mentioned in Chapter 2.5.2, these PDW in the study area, either co-funded by community and Ministry of Multi-ethnic Affairs (MMEA) or fully funded by individual households, were virtually unknown to Mineral Resources Department (MRD) until the inception of this research. With the growth of an excessive and unregulated groundwater drilling and abstraction, the Fiji Government (FG) will need to establish a coordinated approach for interested government department, such as MRD and MMEA, whilst implementing stringent controls of the operation of PDC, through licence or permit systems, to ensure the protection and sustainable management of groundwater systems.

5.1.3 Equitable water allocation

The excess water demand and utilization in the dry season requires the establishment of an equitable allocation mechanism for competing users. The abstraction from Sigatoka River for irrigation by farmers and the excess groundwater abstraction by adjacent communities for domestic use, during the dry period, demonstrate the increasing water demand and competing uses and hence, the establishment of an equitable allocation system is necessary. These, coupled with suggestions of direct recharge from Sigatoka River into several groundwater sources (supported by chemical and

isotopic compositions (section 4.3.3)), reinforces the need for equitable allocation based on the prioritization of water uses during dry periods in relation to the sustainable limits of both groundwater and surface networks (Water Policy Services Pty Ltd, 2006). Further, considering that surface networks will be composed primarily of base flow in the dry period (Green, 1986 & Brassington, 2007), the excess abstraction could create serious adverse impacts on groundwater availability in the long-term. These could affect the availability and usability of water to groundwater-dependent ecosystems, as well as for villages and settlements in the Lower Sigatoka Valley.

5.1.4 Absence of groundwater legislations

As highlighted earlier (section 2.6), the absence of proper legislation is a primary limitation on any attempt to protect and manage groundwater in a sustainable manner. From the estimated groundwater recharge, it is clear that the current groundwater abstraction for drinking and irrigation, particularly in the dry season, requires stringent control and regulation to avoid groundwater depletion (Fetter, 2001). The climatic control on groundwater recharge and the highly uncertain and variable groundwater storage (due to the heterogeneity and complexity of groundwater systems) necessitates the design and enactment of groundwater policies and legislations that emphasise equitable groundwater allocation limits, thus contributes to groundwater protection and groundwater sustainable management.

5.1.5 Climate change

Climate change, a phenomenon predicted with large uncertainties (Singh & Kumar, 2010), may exacerbate the groundwater deterioration and depletion through prolonged dry periods and gradual decline in rainfall recharge. Hetzel et.al (2008) commented that groundwater resources and their long-term replenishment are controlled by long-term climatic conditions, while the impacts of climate change can be observed in more frequent extreme climatic conditions and decreasing groundwater level due prolonged dry periods and downscaled rainfall. In case of Fiji, long-term climatic changes could either lead to more severe dry periods causing drastic fall in meteoric recharge and groundwater level/storage or more wetter periods culminating in abundant recharge

etc. Further, deep groundwater systems are likely to have delayed response to these extreme conditions as opposed to rivers, streams, springs and shallow aquifer systems (Singh & Kumar, 2010). These enhance the vulnerability of groundwater in the study area as the investigated alluvium and fractured systems are shallow groundwater systems as proven by the physical and chemical aspects of this study. Hence, proper management strategies and policies will be urgently required to safeguard the availability and usability of groundwater resources in the long-term.

5.2 Recommendations for groundwater sustainable management

It is critical to the long-term sustainability of water resources that the Fiji Government (FG), being the custodian of all water and mineral resources under the Rivers and Stream Act, Irrigation Act and Mining Act, recognise the scarcity and vulnerability of groundwater resources (to depletion and contamination) by establishing pragmatic and legally binding strategies and mechanisms that promote groundwater protection and sustainable management in the medium to long-term. Despite the degree of uncertainty and large costs associated hydrogeological investigations (Water and Rivers Commission, 2002), the FG should take a proactive approach in groundwater management through:

1. proper characterisation and evaluation of groundwater potential geological units (at appropriate scales), based on inherent variability, extent, thickness, depth, including structural features (fracture systems and/or fault) and using appropriate technologies and methods to establish aquifer boundaries, hydraulic properties, sustainable and allocation limits based on seasonal climates of varying severities (Department of Water, 2010 & Twort et.al., 2000);
2. improving groundwater recharge quantification through improving water resources inventories, data collection at regular and short intervals, and more alluvial aquifer sampling points for both physical and chemical mass balance models;
3. strengthening groundwater monitoring networks and data archiving in conjunction with the monitoring of surface networks through stream and river gauging to determine the interaction of surface and groundwater systems and their responses to climatic conditions;

4. extensive consultation and awareness programmes with community groups and stakeholders to permit a better understanding of their roles in relation to the need to protect and manage groundwater resources in view of the predicted impacts of climate change (Department of Water, 2010);
5. integrating water resources management (IWRM) (Chapter 2.5), including ecological freshwater studies to determine groundwater dependent ecosystems and associated threshold limits in different climatic conditions and hence, necessitating refinement in allocation limits (Department of Water, 2010); and
6. establishing proper and sustainable legal framework that warrants groundwater protection and sustainable management, including the establishment of permits and licence (and penalties) to regulate and controlling the operation of PDC, as well as metering system to regulate groundwater abstraction in rural and/or areas, with emphasis on possible impacts of climate change, (Hawke, 2006 & Water and Rivers Commission, 2002).

Chapter 6: Conclusions

6.1 Thesis conclusions

This research has presented both physical and chemical characteristics of the hydrogeological system underlying the middle Sigatoka valley, Viti Levu, Fiji. The objectives of this study were to: (1) classify the groundwater resource potential of underlying geological materials; (2) determine the dominant hydrochemical facies and origin of groundwater using chemical and isotopic principles; (3) determine the recharge mechanism and rates; and (4) project the sustainability of groundwater resources. This research demonstrates:

1. The study area, underlain by the Oligocene to Middle Miocene Wainimala and Tuva sedimentary groups both of which are deformed and displaced the Nasovatava Fault and capped by Quaternary-Recent Alluvium, is subject to massive water demand and utilisation and, simultaneously, is affected by seasonal climate with pronounced wet and dry seasons from November to April and from May to October, respectively.
2. The physical hydrogeological framework is composed of a surficial confining layer of sandy silt and silt loam, alluvial aquifer systems of unconsolidated sandy gravel around the reaches of the Sigatoka, intermediate confining units of unweathered sedimentary units and fractured basement systems of moderate-highly fractured rock mass. Differing flow and storage estimates of the alluvium and fractured systems, determined from pumping tests, are governed by variable dimension and distribution of aquifer materials, limited recharge and physical heterogeneity of groundwater systems
3. The hydrogeochemistry exhibited two major facies, including (1) shallow system of $\text{Ca}(\text{HCO}_3)_2$ type water dominated by rapid carbonate weathering and adequate meteoric recharge and (2) deeper system of $\text{Na}^+(\text{HCO}_3)$ type water dominated by connate groundwater with some mixing. The stable hydrogen and oxygen isotopic signatures suggest that the valley waters are meteoric in origin that is either flowing into and through the surfaces systems or dispersing at both variable depths and flow rates through alluvial and fractured systems with variable influences of evaporation in vadoze zone and surface environment prior to infiltration.

4. Groundwater recharge mechanisms, include (1) meteoric recharge that is dispersing variably through fractured sedimentary units and (2) seasonally variable leakage from surface water bodies dispersing through alluvial macro-poses. The physical and chemical mass models yielded estimated recharge rates of 0.08 to 0.6 m/month and -0.1 to 0.2 m/month in the wet and dry seasons, respectively.
5. Groundwater protection and sustainable management is likely to be jeopardized by unregulated groundwater drilling by private companies, unregulated groundwater abstraction in the dry period, absence of groundwater legislations and inherent groundwater issues, namely climatic variability, highly complex and heterogeneous hydrogeological conditions.

6.2 Areas of future studies

Several areas of future study are recommended to aid and improve the characterisation of the middle Sigatoka valley hydrogeological system. These topics include:

- characterising the fractured basement systems, namely density and dominant trend, through the use of down-the-hole geophysical logging devices;
- determining the variability in vertical hydraulic conductivity for the fractured sedimentary systems through stratified pumping tests using packer tests;
- establishing gains and losses from adjacent surface sources through stream depletion analysis, in conjunction with of base level recession curves of Sigatoka River through gauging, to determine recharge into alluvial aquifers and base flow component in different climatic conditions;
- establishing the groundwater age, through either tritium, ^3H , or CFC: this will be an added dimension on the sustainability of groundwater resources;
- detailed characterisation of spring sources within the Sigatoka Valley and quantification of water used by adjacent villages and/or farming settlements for drinking: this may be an added dataset for physical water budget;
- identification of recharges sources of the two oxbow lakes; and

- conduct ecological studies to determine groundwater-dependant ecosystems and their groundwater requirements, in relation to seasonal climatic variation, to permit water allocation refinement.

6.3 CONCLUDING REMARK

The replenishment and storage of groundwater in Fiji is highly limited due to dominant climatic control and highly complex/heterogeneous geological systems. Hence, proper groundwater management, including sound hydrogeological investigation and evaluation, reliable monitoring program, proper awareness and pragmatic legal mechanisms, should be established to accurately model the physical and chemical hydrogeological conditions. These are crucial and immediate concerns as climate change, landuse intensification, pollution and rapid population growth, threaten the sustainability of groundwater resources in the long-term.

|---------------------------------------|---------------------|-----|---|
| Quaternary-Recent Alluvium | Silt | ML | Completely Weathered, dark brown to light brown, dry to moist, non-plastic and slightly sticky, compact, massive, fine SANDY SILT. |
| Quaternary Terrace Deposits - Gravels | GRAVEL | GC | Unconsolidated, unweathered, dark grey to light grey andesite-sandstone and basalt clasts, poorly sorted, sub-angular to sub-rounded coarse gravels with minor fine to coarse sand |
| Takaro Conglomerate/Rudite | Conglomerate/Rudite | | Slightly weathered-unweathered, grey to bluish grey, fine to coarse fabric, moderately inclined (20-28°SE), moderately thick to massive, CONGLOMERATE/RUDITE, strong to very strong, subvertical to sub-perpendicular to bedding fractures, moderately widely spaced to closely spaced, very narrow to narrow with stepped roughness, with calcite and quarts infill and no evidence of seepage |
| Cici Sandstone | Sandstone | | Moderately-unweathered, bluish grey-grey, fine fabric, thickly bedded (with laminations), moderately-steeply inclined (24-50° SE), SANDSTONE, sub-vertical to sub-perpendicular to bedding fracture systems, medium to high persistence, moderately widely spaced-closely spaced, tight to moderately narrow aperture (with calcite and quartz infilling) with seepage in some areas |
| Qalimare Limestone | Limestone | | Unweathered-slightly weathered, white to creamy, fine to massive fabric (with coarse volcanoclastics included), sub-vertical, , extremely strong to very strong, LIMESTONE, subvertical fractures, widely spaced, high persistence, wide apertures with rough walls with low-large groundwater flow (with rapid response to rainfall) |
| Tari Formation | ARGILLITE/SANDSTONE | | Unweathered-moderately weathered, brown and bluish grey, fine-coarse fabric, strong to very strong, SANDSTONE/ARGILLITE, moderate-steeply inclined bedding which is thin to moderately thick, joints are closely to moderately wide in spacing, linear fractures perpendicular to bedding. |

Table 1: Engineering geological classification of the mapped units within the study area

| Number | Site Name | Lithological description | Dip/Dip Direction | UNIT |
|--------|-----------|---|-------------------|----------------|
| 1 | Bilalevu | bluish grey and brown, well indurated, moderately fractured, interbedded sandstone and dark brown argillite | 46 NW | Tari Formation |
| 2 | Bilalevu | bluish grey and brown, well indurated, moderately fractured, interbedded sandstone and dark brown argillite | 65 NW | Tari Formation |

| | | | | |
|----|------------------------------------|---|-------|----------------------------|
| 3 | Bilalevu | bluish grey and brown, well indurated, moderately fractured, interbedded sandstone and dark brown argillite | 80 NW | Tari Formation |
| 4 | Sigatoka River Bank, Bilalevu | ~5 m thick unconsolidated yellowish brown sandy silt with gravel bands | - | Alluvium |
| 5 | Sigatoka River Bank, Bilalevu | ~5 m thick unconsolidated yellowish brown sandy silt with gravel bands | - | Alluvium |
| 6 | Bilalevu | brown, well indurated and extremely strong, argillite | - | Tari Formation |
| 7 | Bilalevu | grey, well indurated, unweathered, sandstone matrix supported rudites with dacited and andesite clasts | - | Takaro Conglomerate/Rudite |
| 8 | Bilalevu | brown, well indurated and extremely strong, argillite | - | Tari Formation |
| 9 | Bilalevu | brown, well indurated and extremely strong, argillite | 85 NW | Tari Formation |
| 10 | Bilalevu | grey, well indurated, unweathered, sandstone matrix supported rudites with dacited and andesite clasts | - | Takaro Conglomerate/Rudite |
| 11 | Bilalevu | grey, well indurated, unweathered, sandstone matrix supported rudites with dacited and andesite clasts | 24 SE | Takaro Conglomerate/Rudite |
| 12 | Bilalevu | grey, well indurated, unweathered, sandstone matrix supported rudites with dacited and andesite clasts | - | Takaro Conglomerate/Rudite |
| 13 | Narewa Hill, Bilalevu | grey, well indurated, unweathered, sandstone matrix supported rudites with dacited and andesite clasts | 22 SE | Takaro Conglomerate/Rudite |
| 14 | Bilalevu | grey, well indurated, unweathered, sandstone matrix supported rudites with dacited and andesite clasts | - | Takaro Conglomerate/Rudite |
| 15 | Bilalevu | grey, well indurated, unweathered, sandstone matrix supported rudites with dacited and andesite clasts | 25 SE | Takaro Conglomerate/Rudite |
| 16 | Along Dreke Rd | grey, well indurate, moderately fractured, interbedded sandstone and siltstone | 28 SE | Cici Sandstone |
| 17 | Mavua Hill | creamy to brown, well indurated, massive, calystone and argillite | 26 NW | Tari Formation |
| 18 | Roadcut , Mavua | creamy to brown, well indurated, massive, calystone and argillite | 28 NW | Tari Formation |
| 19 | Roadcut, Mavua | creamy to brown, well indurated, massive, calystone and argillite | 30 NW | Tari Formation |
| 20 | Nabitu Hill | yellowish brown, moderately weathered sandstone | - | Takaro Conglomerate/Rudite |
| 21 | Rararua | grey, well indurate, moderately fractured and interbedded sandstone and siltstone | 24 SE | Cici Sandstone |
| 22 | Qwali Settlement | grey, well indurate, moderately fractured and interbedded sandstone and siltstone | 47 SE | Cici Sandstone |
| 23 | Nakavika junction, Nabaka | grey, well indurate, moderately inclined and moderately fractured, interbedded sandstone and siltstone | - | Cici Sandstone |
| 24 | rock outcrop on a hill at Similaya | grey, well indurated, unweathered, sandstone matrix supported rudites with dacite and andesite clasts | 26 SE | Takaro Conglomerate/Rudite |
| 25 | rock outcrop near Nabaka School | grey, well indurated, unweathered, sandstone matrix supported rudites with dacite and andesite clasts | 24 SE | Takaro Conglomerate/Rudite |

| | | | | |
|----|--|---|-------------|----------------------------|
| 26 | rock outcrop near Oxbow Lake, Nabaka | grey, well indurated, unweathered, sandstone matrix supported rudites with dacite and andesite clasts | 22 SE | Takaro Conglomerate/Rudite |
| 27 | Jubairata Meander, Dubalevu | grey, well indurated, unweathered, sandstone matrix supported rudites with dacite and andesite clasts | 20 SE | Takaro Conglomerate/Rudite |
| 28 | roadcut at Vunarewa | interbedded bluish grey sandstone, dacitic tuff and argillite, moderately fractured | - | Tari Formation |
| 29 | Toga | white to creamy, well indurated, massive with volcanicalstic inclusions, fractured Limestone | subvertical | Qalimare Limestone |
| 30 | Toga | white to creamy, well indurated, massive and moderately fractured Limestone | subvertical | Qalimare Limestone |
| 30 | Toga | white to creamy, well indurated, massive with volcanicalstic inclusions, fractured Limestone | subvertical | Qalimare Limestone |
| 31 | Toga | white to creamy, well indurated, massive with volcanicalstic inclusions, fractured Limestone | subvertical | Qalimare Limestone |
| 32 | Toga | white to creamy, well indurated, massive and moderately fractured Limestone | subvertical | Qalimare Limestone |
| 33 | Toga | white to creamy, well indurated, massive with volcanicalstic inclusions, fractured Limestone | subvertical | Qalimare Limestone |
| 34 | Mataukaba, Vunarewa | interbedded argillite, sandstone and dacitic tuff | - | Tari Formation |
| 35 | Bedrock high near Sigatoka River, Nabitu | grey, well indurated, unweathered, sandstone matrix supported rudites with dacited and andesite clasts | 28 SE | Takaro Conglomerate/Rudite |
| 36 | Navala, Mavua | grey, well indurated, vesicular basaltic flow with abundant quartz amygdals | - | Tari Formation |
| 37 | Ami Chand's residence | bluish grey, well-indurate, moderately fractured, thickly bedded and interbedded sandstone and siltstone | 43 SE | Cici Sandstone |
| 38 | Jubaitara hill | yellowish brown, moderately weathered, moderately fractured, thickly bedded and interbedded sandstone and siltstone | 35 SE | Cici Sandstone |
| 39 | Dubalevu | bluish grey, well-indurated, moderately fractured, thickly bedded and interbedded sandstone and siltstone | 40 SE | Cici Sandstone |
| 40 | Dubalevu | bluish grey, well-indurated, moderately fractured, thickly bedded and interbedded sandstone and siltstone | 45 SE | Cici Sandstone |
| 41 | Dubalevu | bluish grey, well-indurated, moderately fractured, thickly bedded and interbedded sandstone and siltstone | 47 SE | Cici Sandstone |
| 42 | Dubalevu | bluish grey, well-indurated, moderately fractured, thickly bedded and interbedded sandstone and siltstone | 46 SE | Cici Sandstone |

Table 2: summary of mapping localities

APPENDIX D: Additional Geophysical Information & Results

1. Methods background information

- **Electromagnetic (EM)**

EM, regarded as an inductive technique due to the variable magnetic fields induced by the emission of variable electrical currents into the subsurface, have numerous arrangements, time-domain and frequency. In this investigation, frequency domain EM34-3 Geonics equipment was used.

FIGURE 1. Induced current flow (homogeneous halfspace).

Figure 1: set-up of transmitter and receiver coils with alternating electric current emitted in the in the Tx

This method of entails the emission of alternating electrical current through a transmitter coil (Tx). These time-varying currents generate a primary magnetic field and upon interaction with subsurface materials induces very small currents, generating the secondary magnetic field, which are both sensed by the receiver coil (Rx) (Figure 1) (McNeil, 1980). Hence, the secondary field depends on electrical properties of the subsurface, namely degree of saturation, conductivity of pore fluids, clay minerals and reflectors (Nobes, 1996). The strength of the secondary response is separated into two components: in-phase response, and quadrature response (Nobes, 1996). The in-phase component, identical to the signal measured by metal detectors and sometimes called the “metal detector” mode, is expressed as parts per thousand (ppt) and measures the strength of the transmitted field. In the absence of metals, the in-phase mode is generally small and highly variable, but can be sensitive to ground disturbances, particularly the presence of small amounts of metal (Nobes, 1996). The quadrature response yields a measure of the bulk electrical properties and is controlled by the particular frequency of the EM equipment. The quadrature

response, expressed as an apparent electrical conductivity and measured in mS/m, will be used in this survey in relation to delineating subsurface disturbances, which may represent a fault zone or an alluvial gravel bed.

- **Electrical Resistivity (ER)**

ER measurements of the subsurface, pioneered by the Schlumberger brothers in the 20th century (Nobes, 1996), is conducted by injecting currents through two electrodes A and B and the resulting potential through M and N. Electrical methods, comprising vertical electrical sounding (VES) and electrical profiling (EP), require galvanic ground contacts together with a resistivity equipment and an electrical power source. For this survey, VES method, mostly applied on approximately horizontal earth and due to its favorable potential of producing subsurface thicknesses with their corresponding resistivities (Ernstson & Kirsch, 2009), was used. The vertical resistivity layering is warranted by the step-wise increase in current-injecting electrode AB spacing, which, in turn, results in a deeper penetration of electric current and higher resolution of the subsurface profile. Accuracy of electrical methods are always influenced by the principle of equivalence, topographic effects and cultural noise such as power lines, metal fences and buried pipes (Nobes, 2009). ER methods are most used in smaller scale surveys mainly because the depth of penetration depends on the electrode separation and large and often impractical separations must be used to obtain large depths of penetration. However, the resultant resistivity profiles generated from these surveys represent the resistivity sum of all geologic layers above a particular sample point in the subsurface as influenced by factors mentioned above.

2. Survey site conditions

Survey sites and orientation of survey lines were selected and designed carefully to produce satisfactory subsurface profile resolution so as to achieve most of the survey objectives. It should also be noted that ER surveys were conducted several days after Tropical Cyclone Mick (TCM), which caused widespread flash flooding around the SV.

Figure 2: areas of geophysical survey as governed by the (1) E-W orientation of the abandoned meander at Dubalevu and the existence of currently used SVRD wells (2) orientation of the ENE-WSW sinistral Nasovatava fault at Tubakeli and (3) NW-SE inferred fault splay and along Bila Rd (superimposed on 1:10 000 IKONOS sateline image)

- DUBALEVU

Dubalevu is located on an approximately 800 m wide E-W trending incised and now-abandoned meander and bounded by the highly deformed, steeply inclined Cici Sandstone (CS). The survey was conducted on a farm, 500 m from the Tubairata Rd junction. The abandoned meander is capped by overbank materials, comprising dark brown, fine grained, non-sticky, non-plastic and well-compacted silt loam. Several existing wells (Figure 3), drilled during the SVRDP, were penetrated in series of buried river channels and the distribution of which was localized in the eastern part of the valley. This survey, however, presents an opportunity to determine the spatial extent or continuity of the QRA, particularly the buried river channels, in the western side of the valley and to establish if there are

fractured rock aquifers occurring at depth. However, SVRDP wells water levels and lithological data from these wells were used a priori for the geophysical survey and groundwater exploration drilling.

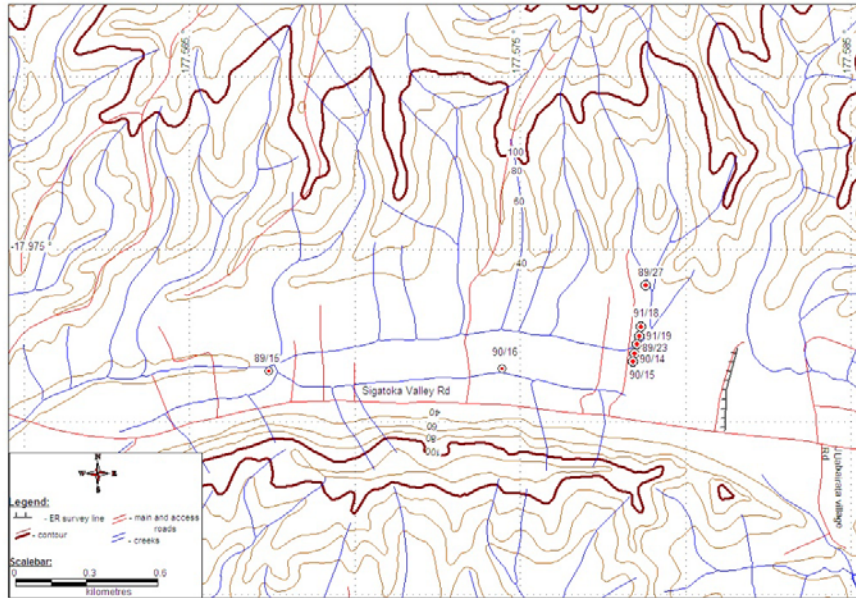

Figure 3: ER survey line – Dubalevu

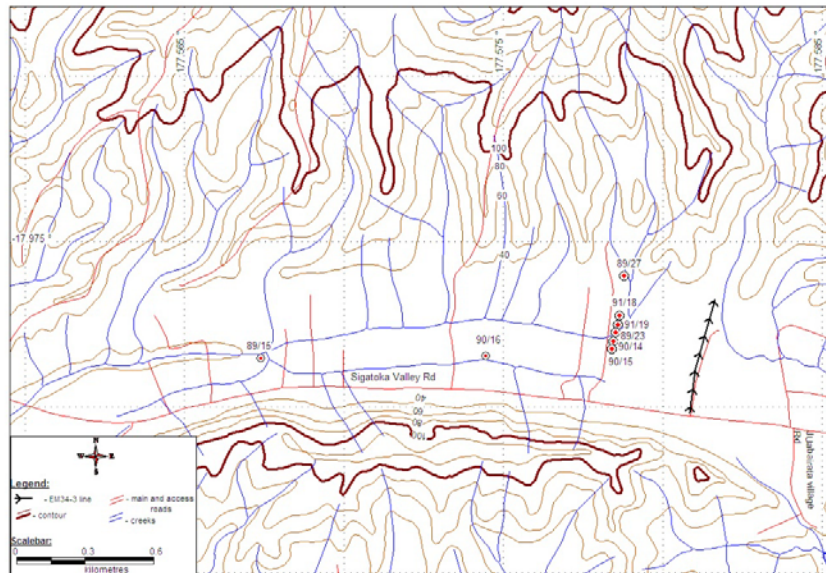

Figure 4: EM 34-3 survey line - Dubalevu

- **Bilalevu**

Survey was conducted on two separate localities, (1) at Tubakeli and (2) along Bila Rd, within the Sigatoka meander at Bilalevu. The selection of these two survey sites were to:

- explore and assess the hydrogeological potential and the variability of the two different underlying geological units, namely Takaro Rudite and Conglomerate of the TSG and Tari Formation of WG;
- identify any fault or shear zone associated with the sinistral ENE-WSE Nasovatava fault and one of its fault splays, which is inferred to have propagated perpendicular in SSE orientation along Bila Rd; and
- assess depth and thickness of the alluvial aquifer (if any) and establish the variability in subsurface materials as a possible function of continuous shifts in the ancient river systems

At Tubakeli, the survey was conducted on vegetable farms, located on alluvial terrace comprising predominantly overbank flood deposits, and underlain by the Takaro Conglomerate/Rudite (TCR). The alluvial flat, on which the two opposite farms are located, is characterized by dark brown to brown silty loam and is located adjacent to the Nasovatava Creek and an oxbow lake, and through which the ENE-WSW NF runs. Despite having eight (8) private wells around the area, only one (1) well drill-log (SVRDP well 89/27 and now abandoned due to poor quality) was available, which was inconclusive in the exploration of any fault or shear zone associated with the NF at Tubakeli. Hence, there were insufficient data to establish any geological constraint within the area and necessitating this survey. The survey lines were oriented E-W and N-S to detect perpendicular subsurface structural features (if any).

Along Bila Rd, the survey was conducted on two farms, 250 m apart, located towards the southern end of the meander and the survey lines were oriented E-W so that it could go through the inferred N-S fault splay associated with the NF. The farms are capped by light brown to dark brown silty, non plastic, slightly sticky silt loam with minor fine sand and is underlain by the Tari Formation (TF). The area has one (1) privately owned groundwater well and is drilled into unconsolidated silty sand to a depth of 20 m.

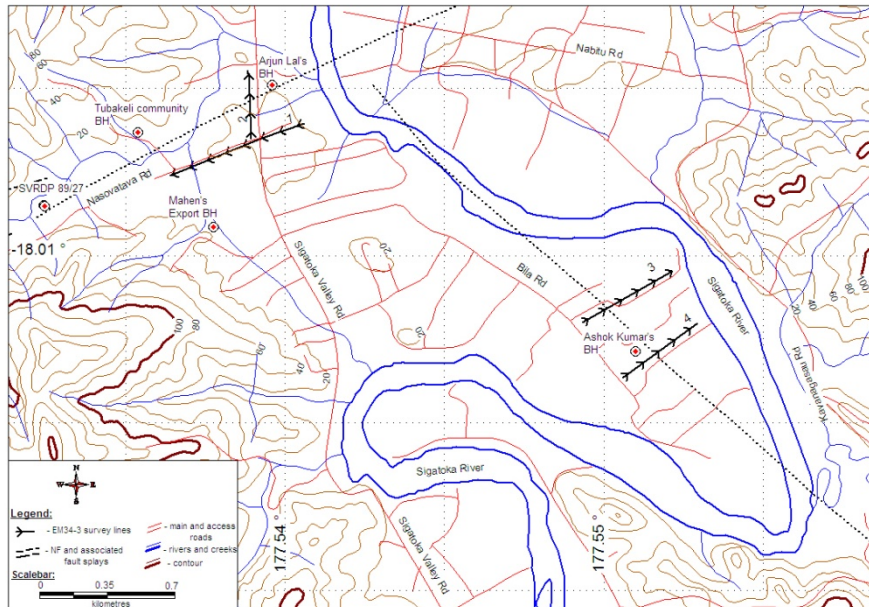

Figure 6: EM survey lines and numbers - Bilalevu

3.2.4 Survey Design, Instrumentation & Data Analysis

Prior to the survey, numerous field visits were carried out to identify the best survey areas and during which agricultural officers were consulted on areas where groundwater wells are necessary for irrigation. These visits also served to inform farmers about the project and seek land-access permission. These was followed by the measurement of standing water levels from nearby borehole, temperature and electrical conductivity using a TLC Solinist dipper to develop a priori (shown earlier in Table 3.2 & 3.3) and upon which the orientation of both

survey methods, as well as the electrode spacing of ER method, are controlled. Relatively flat areas with adequate space and minimal cultural noise were selected as shown by Figure 2. Geological reconnaissance with the assistance of aerial photo and satellite images interpretations were also conducted with the aim to understand the geological and tectonic setting of the larger landscape, with special attention given to geomorphic and structural features pertinent to groundwater occurrence (Sequeira & Mendoza, 2003). It was also critical that both the surveys were conducted under good weather conditions to ensure the safety and security of staffs, as well as the protection of costly geophysical equipment. Shown below, the electrical resistivity profiles, from both dipole-dipole strong gradient (DDSG) and Schlumberger array, and vertical and horizontal electromagnetic responses (raw and tapered) generated at Dubalevu, and Tubakeli and Bila Rd in Bilalevu.

Appendix E: Permeability test results

Soil samples were collected from Dubalevu, Tubakeli and Bila Rd following the digging of mud-pits and prior to the drilling of wells 10/07, 10/11 and 10/15 respectively (Figure 1).

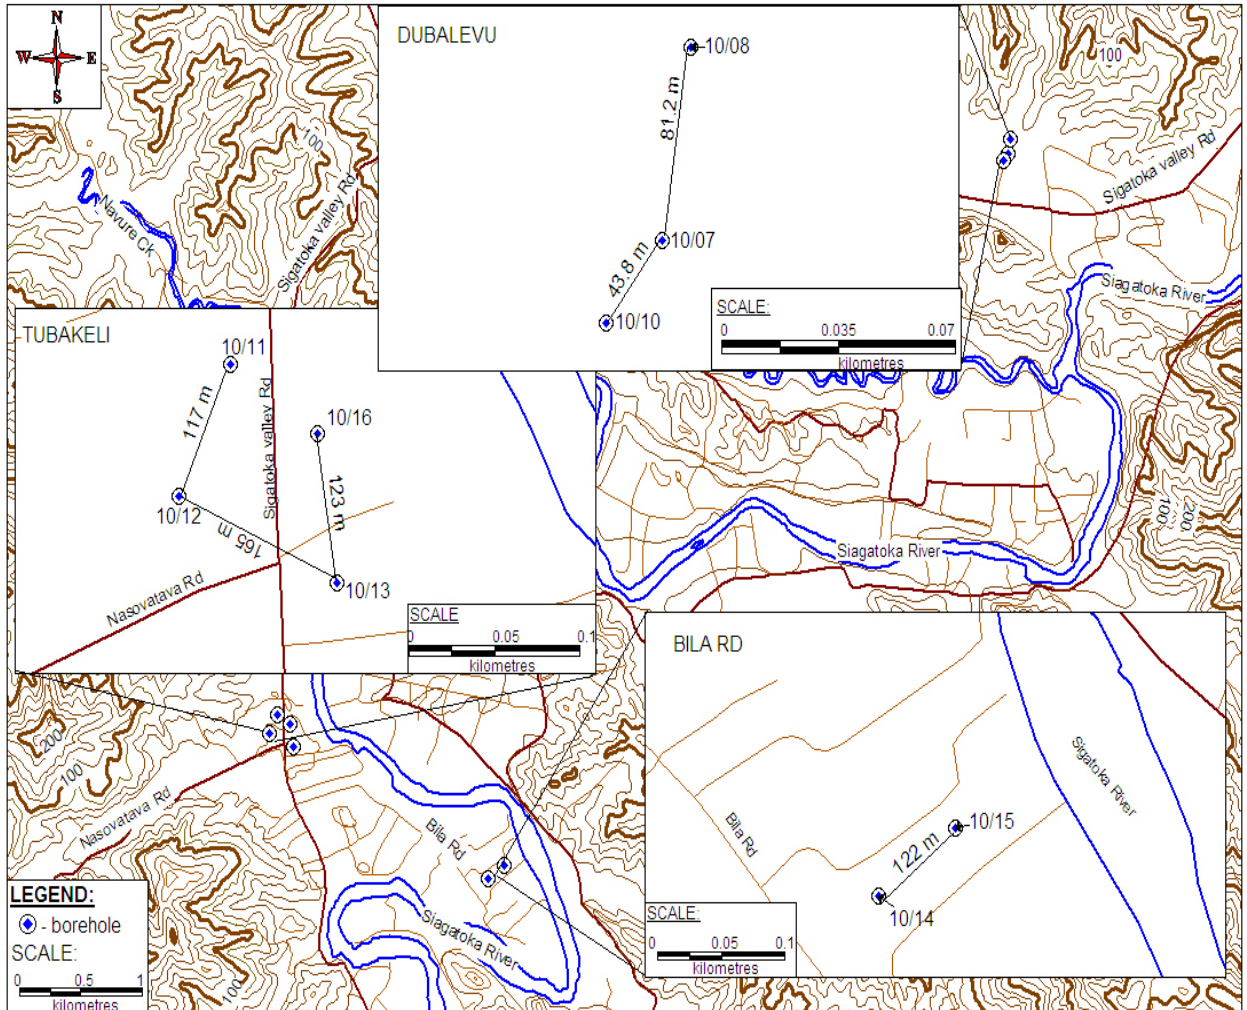

Figure 1: location of wells 10/07, 10/11 and 10/15 where the test soils were collected

$$K = (a/A) \times (L/t) \times \ln\{h_0/h\} \quad K' = 2.3 (a/A) \times (L/t) \times \log_{10}\{h_0/h\}$$

where K = hydraulic conductivity (m/s)

a = standpipe area (m^2)

A = sample cross sectional area (m^2)

L = sample thickness or height (m)

h_0 = initial head above top of sample (m)

h = measured head during or at the end of test (m)

t = elapsed time from h_0 to h (sec)

Appendix G: Pump-test Data

Evaluation of groundwater via pumping test was conducted on 6 of the 9 drilled wells. Well 10/10 and 10/11 were monitored full time for drawdown and recovery analysis due to the difficulty of monitoring pumping wells 10/07 and 10/12, respectively due to the vibration of the mono-pump column pipes inside the borehole and thus, preventing the free insertion and retrieval of depth probes during the test. Well 10/07 was monitored when 10/08 was pumped; well 10/12 was monitored when well 10/13 was pumped; well 10/15 was monitored when well 10/14 was pumped. Well 10/15, due to no observed drawdown at well 10/14, was conducted as single well test. The estimation of aquifer properties were estimated using Theiss match curve and Cooper-Jacob methods mainly because these wells were penetrating confining aquifers and exhibited non-equilibrium flow conditions. Please note that the average aquifer thickness between the pumping well and observation well is used to calculate K or hydraulic conductivity.

1. Theiss match curve where matchpoint is found at $1/u = 1$ and $W(u) = 1$

a. $T = Q/(4 \times 22/7 \times d)$

Where T is transmissivity (m^2/day)

Q is discharge (L/day)

d is drawdown in (m) at matchpoint

b. $S = (4 \times T \times t)/r^2$

Where S is storativity (dimensionless)

T is transmissivity (m^2/day)

t is time at matchpoint ($\text{min}/1440$)

r is distance from pumping well (m)

c. $K = T \times b$

Where K = hydraulic conductivity (m/day)

T is transmissivity (m^2/day)

b is thickness of the aquifer

2. Copper-Jacob straight line methods

a. $T = (2.3 \times Q)/(4 \times 22/7 \times \Delta s)$

Where T is transmissivity (m^2/day)

Q is discharge (L/day)

Δs is change in storage in a log cycle (m)

b. $K = T \times b$

Where K = hydraulic conductivity (m/day)

T is transmissivity (m^2/day)

b is thickness of the aquifer

Table 8: drawdown at observation well 10/12 during constant-rate pumping of well 10/13

Figure 8: drawdown at observation well 10/12 during the constant-rate pumping of well 10/13

WELL 10/11, Tubakeli, Bilalevu

This well was monitored full time for drawdown and recovery due vibration of column pipes in pumping well 10/12 and hence, preventing the measurement of instantaneous drawdown.

Table 1: physical water balance calculation

Appendix I: Individual Chemical Results

Chemical sampling, as mentioned in section 3.5, was conducted on monthly basis. Due to the spatial extent of the study area, cost of analysis and logistical costs, coverage of the entire field area was difficult. Consequently, sites were sampled, at least, twice in the course of the project. The samples were then grouped in to location areas, namely Bilalevu (B), Dubalevu (D), Nabaka (Na), Nabitu (Nb) Siminilaya (S) and Vunarewa (V) and were given unique ID for ease of referencing. A total of 93 samples were collected during the course of the project (September, 2009 – January, 2011) and the individual results are provided below with the Site ID added for reference. The table below presents the sites, location, physical parameters and site ID before the individual results area provided. As discussed earlier in sections 3.5 and 4.3, the samples were averaged, to provide a snapshot of hydrochemistry of the sampled water source.

| Site, Location | Depth | Location | Source | ID | pH | EC | Salinity | Temp |
